APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Viral Hemorrhagic Fevers

Author(s): Jill E. Holdsworth, MS, CIC

Inova Mount Vernon Hospital
Alexandria, VA

Published: October 4, 2016

Abstract

Viral hemorrhagic fever (VHF) describes a spectrum of illness ranging from fever with minor evidence of coagulopathy to a syndrome of hemorrhagic diathesis, multiorgan system failure with severe shock, and death. It is typical to see overall vascular system damage, hemorrhage and overall impairment of the body's ability to regulate. The etiologic agents of VHF constitute four distinct families: (1) Flaviviridae (yellow fever virus [YFV], dengue fever); (2) Bunyaviridae (Crimean-Congo hemorrhagic fever, hantavirus including Sin Nombre, Rift Valley fever); (3) Filoviridae (Marburg, Ebola); and (4) Arenaviridae (Lassa, New World arenaviruses). Combined, these viruses have both a significant and varied geographic distribution and are often zoonotic. Residence in or travel to endemic areas, nosocomial transmission, and bioterrorist attacks are all potential risks of these diseases. Once suspicious of an index case, appropriate transmission-based precautions, reporting, and preemptive treatment should be initiated. Confirmation is established in Biosafety Level 4 (BSL4) laboratories. Many agents of VHF lack effective prevention or treatment. Infection prevention measures are imperative for containment and the protection of healthcare workers (HCWs) and others. Development of effective treatments and vaccines remain the subject of intensive study.

Key Concepts

- Hemorrhagic fever viruses have broad but specific geographic distributions.
- Animal reservoirs are important zoonotic sources that vary in each group of viruses; insects often serve as vectors.
- Viremic human hosts can serve as reservoirs for some VHFs.
- Incubation periods are 2 to 21 days.

- In severe cases, patients present with fever, nausea, vomiting, myalgia, petechiae, bleeding, and shock.
- Medical care, infection prevention practices, and public health measures are all critical in managing patients with suspected VHF.
- Appropriate techniques of donning & doffing personnel protective equipment (PPE) is key to preventing transmission of Ebola.
- YFV vaccine is the only licensed vaccine for VHF.
- Treatment of infection is generally supportive.
- Patients infected with VHF should be placed in contact and droplet precautions with gown, gloves, mask, and eye protection; airborne infection isolation (AII) is recommended in certain instances where aerosolization is expected.
- Without a risk of known exposure, bioterrorism should be suspected in patients with VHF.

Background

Hemorrhagic fever has been documented throughout ancient and modern history. The earliest description of symptoms now thought to be dengue was in a Chinese encyclopedia from the Chin Dynasty (221–207BC). The first reported pandemic of dengue-like illness occurred in the late 18th century in three continents.[1] The worst outbreak of VHF in U.S. history occurred in Philadelphia in 1793 when yellow fever virus devastated the city, killing more than 5000 people—10 percent of the city's population—in just a few months. The nation's capital was shut down, and President Washington moved the government out of the city to escape the epidemic. Public panic was rampant, people walked in the middle of the streets to avoid infected houses, and friends avoided speaking to each other out of fear of disease transmission.[2] Yellow fever Virus continued to plague the United States intermittently until the development of a vaccine in 1930.

On the other end of the historical timeline, hantavirus pulmonary syndrome (HPS) was first recognized in 1993 in the four corners region of the southwestern United States when a cluster of cases of influenza-like-illness showed up that progressed quickly to a severe respiratory disease. The Special Pathogens Branch of the Centers for Disease Control and Prevention (CDC) identified a new virus, Mueto Canyon virus, subsequently named Sin Nombre virus (SNV), as the etiologic agent. The disease caused by the virus was named hantavirus pulmonary syndrome. Retrospective analysis revealed that earlier cases of respiratory distress syndromes dating to 1959 were caused by HPS.[3] In 2012, ten cases of hantavirus were confirmed in California. All ten cases were linked to recent visitors to Yosemite National Park.

More recently, in 2014, the largest outbreak of VHF in history occurred in West Africa. Total cases reached above 28,000 with more than 11,000 deaths, with Guinea, Sierra Leone and Liberia, the main countries affected. The United States saw its first laboratory-confirmed case of VHF caused by the Ebola virus in September 2014 in Dallas, TX. The man had recently traveled from Liberia and was not symptomatic during his travel. Testing was recommended by the CDC and confirmed Ebola. All close contact were monitored by health officials for 21 days after exposure. In October 2014, a HCW at the Texas hospital tested positive for Ebola. The HCW was isolated after initially reporting symptoms, recovered and was discharged. Also in October 2014, a second HCW at the Texas hospital tested positive for Ebola. This HCW had traveled by air to Cleveland, returning to Dallas. All passengers and

crew completed the 21-day monitoring and the patient recovered and was discharged. Additional information relate to these cases may be located at **www.cdc.gov/vhf/ebola/outbreaks/2014-west-africa/united-states-imported-case.html**.

Basic Principles

VHF is caused by a diverse group of small RNA viruses from four major viral families that are found in different geographic areas as shown in Table 96-1. The viruses naturally reside in an animal reservoir host or arthropod vector. Person-to-person spread can occur from body fluid contact.[4] Many have potential for weaponization, and worldwide health systems take part in ongoing preparation for any case of intentional release of these agents.[5]

VHF can range from asymptomatic to a mild febrile illness to the hemorrhagic syndrome, including fever with severe shock, multiorgan system failure, and death. Although bleeding is a dramatic finding in these diseases, it is rarely life threatening. The impaired function of multiple organ systems is the primary marker of morbidity and mortality. Etiological viral agents of VHF are taxonomically identifiable by four groups [4]:

1. Flaviviridae—YFV, dengue fever, dengue hemorrhagic fever (DHF), Omsk hemorrhagic fever (OHF), and Kyasanur Forest disease (KFD)
2. Bunyaviridae—Congo-Crimean hemorrhagic fever (CCHF), HPS, hemorrhagic fever with renal syndrome (HFRS), and Rift Valley fever (RVF)
3. Filoviridae—Marburg and Ebola
4. Arenaviridae—Lassa fever and New World arenaviruses, including Guanarito, Sabia, Junin, and Machupo.

Viral Hemorrhagic Fevers: Cause And Effect

ETIOLOGIC AGENTS AND VECTORS

Table 96-1 details the most important etiologic agents, geographical distribution, and other features of VHF viruses. The agents are RNA viruses covered, or enveloped, in a fatty (lipid) coating. Virus survival is dependent on an animal or insect host: their natural reservoir. Humans may become infected when they come into contact with infected hosts or excreta and may subsequently transmit the virus to one another. Human cases of VHFs occur sporadically and irregularly and outbreaks cannot be easily predicted.[4]

Table 96-1 Characteristics of Viruses Causing Viral Hemorrhagic Fever

Virus	Family	Geography	Vector	Host	Epidemiologic Features
Yellow fever virus	Flaviviridae	Central and South America, Africa	*Aedes*and *Haemagogus* mosquito	Monkeys, humans	Three cycles of transmission by vector: urban (human to human), intermediate, (savannah) and sylvatic (jungle, monkey to human)
Omsk hemorrhagic fever	Flaviviridae	Western Siberia	*Dermacentor*ticks	Small mammals	Direct contact with ticks; contact with blood, feces, or urine of an infected or dead rodent; milk of infected goat or sheep

Kyasanur Forest disease	Flaviviridae	India	*Haemaphysalis*ticks	Small mammals, monkeys, birds, bats, cattle	Direct contact with infected ticks, deforestation for cattle grazing increases tick population
Dengue	Flaviviridae	Tropical America, Africa, Asia	*Aedes*mosquito	Humans	Transmitted as is urban yellow fever
Crimean-Congo hemorrhagic fever	Bunyaviridae	Russia, Middle East, Sub-Saharan Africa, Asia, Balkans	*Hyalomma*ticks	Cattle, sheep, goats, hares	Agricultural/cattle workers at risk; has caused healthcare-associated outbreaks
Hantavirus	Bunyaviridae	Worldwide	None	Rodents	Occurs through contact with infected rodents, rodent excreta, often aerosolized material; unlikely spread from person to person
Rift Valley fever	Bunyaviridae	Sub-Saharan Africa, Madagascar, Middle East	*Aedes*mosquito	Cattle, sheep, small mammals	Epizootic outbreaks occur in times of elevated rainfalls and persistent flooding
Marburg	Filoviridae	Sub-Saharan Africa	Not known	Not known	Humans only known source of infections; body fluids are highly infectious
Ebola	Filoviridae	Sub-Saharan Africa	Not known	Not known	As with Marburg
Lassa	Arenaviridae	West and Central Africa	None	Rodents	Occurs through contact with infected rodents, rodent excreta, often aerosolized material; may spread person to person, healthcare-associated outbreak
Guanario	Arenaviridae	Venezuela	None	Rodents	Transmitted as in Lassa
Sabia	Arenaviridae	Brazil	Not known	Not known	May spread person to person
Junin	Arenaviridae	Argentina	None	Rodents	Transmitted as in Lassa
Machupo	Arenaviridae	Bolivia	None	Rodents	Transmitted as in Lassa

*Initial outbreak in 1967 was associated with exposure to tissue cultures or kidneys of infected African green monkeys imported for vaccine preparation, but subsequent work does not suggest that these animals are natural virus reservoirs.

Flaviviridae

YFV is an arthropod-borne virus with three known transmission cycles. In sylvatic YFV, transmission occurs between non-human primates and mosquito species, usually via mosquitos from monkeys to humans during occupational or recreational activities in the jungle. Intermediate transmission cycle occurs from tree hole-breeding *Aedes* species to humans. This cycle usually transmits from monkeys to humans or from human to human via mosquito. Urban YFV is passed between humans and urban mosquitos.

The vector for dengue fever is the female Aedes mosquito found predominately in tropical and subtropical areas. Specifically, this group B arbovirus is transmitted by *Aedes aegypti* and *Aedes*

albopictus. There are four dengue virus serotypes: DEN-1, DEN-2, DEN-3, and DEN-4.[6]

OHF is transmitted by *Dermacentor* ticks, water voles (*Arvicola terrestris*) and non-native muskrats (*Ondatra zibethica*).

KFD is transmitted primarily by the *Haemaphysalis spinigera* tick.

Bunyaviridae

CCHF, caused by the tick-borne virus *Nairovirus*, is primarily transmitted to people from ticks and infected livestock animals. Human to human transmission is possible when close contact with blood and body fluids occur.

Hantavirus is transmitted from virus shed in rodent excreta by breathing in the virus when stirred up in the air or touching a mucous membrane after contact with rodent excreta or nesting materials. Each hantavirus has a unique rodent host. In the United States, rodents including the deer mouse (*Peromyscus maniculatus*), cotton rat (*Sigmodon hispidus*), rice rat (*Oryzomys palustris*), and whitefooted mouse (*Peromyscus leucopus*) have been found to carry the agent responsible for HPS, and several other rodent reservoirs are linked to HFRS. *Aedes* mosquitoes spread RVF.

HPS is very rare, but cases have been reported in all areas of the United States except Alaska and Hawaii.

Rift Valley Fever (RVF) affects domestic animals (cattle, buffalo, sheep, goats, and camels) and humans. RVF, a mosquito-borne virus, is most common during times of heavy rainfall. The excess rainfall allows mosquito eggs to hatch. The mosquitos, naturally infected with the RVF virus, then transfer the virus to livestock.

Filoviridae

A vector for Marburg and Ebola has not been confirmed. Recent studies indicate that fruit bats in Africa and Uganda are a reservoir. [7]

Five subtypes of Ebola virus exist, four of which have caused disease in humans: Ebola-Zaire, Ebola-Sudan, Ebola-Ivory Coast, Ebola-Bundibugyo, and Ebola-Reston.

Arenaviridae

Arenaviridae are transmitted through close contact with food or household items contaminated with rodent excreta. The reservoir for Lassa virus is the “multimammate rate” of the genus *Mastomys*. Some, including Lassa and Machupo, may be spread by person-to-person contact and laboratory transmission via contact with blood or other body fluids. Airborne transmission has been described. [4]

Epidemiology

Because the VHF viruses have a substantial geographic distribution, widespread travel has increased the probability that HCW will care for patients infected with these diseases. Between 1996 and 2006, the World Health Organization (WHO) reported outbreaks of CCHF in 6 of 10 years in locations in South Africa, South Asia, and Eastern Europe. Ebola epidemics have been noted with a high frequency in several countries in Africa, most recently in the Democratic Republic of Congo in December 2008.[5] The closely related Marburg hemorrhagic virus has been the cause of imported disease cases from Uganda

to The Netherlands and United States in 2008.[8] An estimated 200,000 cases of YF occur each year in South America and Africa.[6] This epidemiologic frequency, coupled with the threat of bioterrorism, makes it imperative for the clinician to understand the nature and course of these diseases. The WHO currently tracks outbreaks of Ebola, CCHF, Lassa fever, YF, RVF, and dengue fever.[5] Hantaviruses have a worldwide distribution and originally were known to cause HFRS. By 2007, 465 cases of HPS had been reported in the United States since its initial description.[3]

PATHOGENESIS AND CLINICAL FEATURES

The precise pathogenesis for VHF varies according to the specific etiologic agent; immunologic and inflammatory mediators are thought to play an important role. In DHF, an immune-mediated pathogenesis is thought to play a role when an individual previously infected with dengue is exposed to a heterologous serotype. In other VHFs, potential pathophysiologic mechanisms include disseminated intravascular coagulation (DIC), consumptive coagulopathy, and hepatic dysfunction.[9] All VHFs can produce thrombocytopenia. Although the major target organ is the vascular endothelium, some may induce platelet dysfunction.

VHFs are caused by agents that have pronounced aerosol stability and high infectivity.[10] Fortunately, they are not highly transmissible among humans without direct physical contact with infected fluids, presumably because virus-containing aerosols are not easily generated by those infected. During the 2014 Ebola outbreak, N-95 respirators were recommended because of the potential to perform a procedure that would cause aerosolization and thus needing a higher level of protection on moment's notice. Still, they retain a potential for use as biological agents. Programs that have developed weaponized forms of VHF have existed for many years, some in production until recently. For example, the former Soviet Union produced large quantities of Marburg, Ebola, Lassa, Junin, and Machupo viruses until 1992, and the United States weaponized RVF and YF as part of a biological weapons program that was ended in 1969.[11]

Most VHF viruses cause disease during the period of viremia. When the viremia clears, the patient recovers. The exceptions are the dengue and hantaviruses, which have an immunopathologic basis.[1,3,4]

In VHF, hematologic manifestations may be different from those found in sepsis. A vascular syndrome marked by endothelial dysfunction or damage appears to be the primary mechanism of hemorrhage. Bleeding can occur in the absence of DIC. VHF viruses share a similar syndrome of diffuse capillary damage and coagulation dysregulation. Pro-inflammatory cytokine production, especially tumor necrosis factor (TNF)-α, has also been a consistent finding.[10,12] Cytopathic effects from VHF viruses vary among agents, some causing a marked cytopathic effect, whereas others show little evidence of cell destruction. The major organs involved include the kidney, brain, and liver.

Flaviviruses have an unidentified pathogenesis, but Kupffer cells in the liver appear to be the first cells targeted. Replication and subsequent cellular damage take place in the hepatocytes and myocytes.[13]

There is hepatocellular necrosis with sparing of the central vein and portal areas. The eosinophilic degeneration of hepatocytes leads to the formation of Councilman bodies. Bradycardia and arrhythmias are related to myocyte infection. Albuminuria and renal insufficiency reflect prerenal processes and parenchymal invasion. Renal tubular necrosis can develop in advanced illness.

Bunyaviruses exhibit varied effects dependent on the viral agent. CCHF causes massive hemorrhage and DIC but is not as cytotoxic as RVF. There is necrosis seen in hepatocytes expressing viral antigen, but the overall mechanism of disease remains poorly understood.

In HPS, the heart and lung are the target organs of infection with extensive viral replication occurring in endothelial tissues, particularly the pulmonary vascular bed. Subsequent damage to the capillary endothelium produces severe pulmonary edema and hypotensive shock. Typical laboratory findings include left shift in WBCs, hemoconcentration, neutrophilic leukocytosis, thrombocytopenia and circulating immunoblasts.

The RVF virus is very cytotoxic, and rapid cell death occurs in all mammalian cells tested, including human endothelial cell cultures.[14] In studies with monkeys, a reliable predictor of outcome was the secretion of interferon (INF)-α. If levels were detectable within 12 hours of infection, the course was mild. With a later onset of secretion, severe disease and DIC were seen.[15] Delay in the INF response might allow for more extensive infection and cell death, triggering the severe form of the disease.

Filoviruses have a combined cytokine effect and cytotoxic effect. Cytokine release by macrophages, notably TNF-α, plays a role in the alterations in endothelial permeability.[6] Cytokines are suspected in the severe apoptosis of lymphoid organs seen in Ebola infections.16 Cytotoxic effects are seen in parenchymal cells in multiple organs, including the endothelium. DIC is associated with filovirus infection. Animal studies have demonstrated a slight increase in survival from Ebola with the use of activated protein C as a successful adjuvant treatment for sepsis in humans, supporting the hypothesis that Ebola and sepsis share some common pathways.[17]

Arenaviruses are not highly cytopathic. They have been shown to disrupt cellular function without damaging the cell.[6] The degree of cellular dysfunction exceeds the pattern of cellular damage, suggesting an underlying mechanism. This pattern of dysfunction may also explain the finding of cardiac depression that can accompany arenavirus infections. Thrombocytopenia and platelet dysfunction are associated with bleeding episodes. There is no evidence of major coagulation pathway defects or DIC in arenavirus infections.[11] Thrombocytopenia and platelet dysfunction are associated with bleeding episodes.

CLINICAL MANIFESTATIONS

Infections with viruses causing VHF are frequently asymptomatic, but when the infections are symptomatic, there is typically abrupt onset of fever, chills, headache, myalgia, and malaise. A minority of patients progress to a hemorrhagic syndrome. Travel history, incubation period, and the distinguishing clinical features outlined here can help to suggest the viral etiology.

Flaviviridae

YFV is distributed in tropical South America and Africa. It has an incubation period of 3 to 6 days. Bradycardia despite fever (Faget's sign) is characteristic. Disease course includes three periods: infection, remission, and intoxication. The period of infection may be asymptomatic or present with influenza-like illness symptoms, fever, myalgia, headache, appetite loss, nausea, or vomiting. The symptoms of the primary infection remit on days 3 to 4 and are termed the period of remission; this is marked by an improvement in fever, nausea, and headache. Most patients will recover at this point without any further sequelae. Some patients, however, will continue into the period of intoxication after a remission that lasts for several hours up to 2 days before the fever recurs. The intoxication occurs in

approximately 15 percent of patients[18] and includes a fever (>40°C), severe headache and myalgia, hemorrhagic diathesis, myocardial invasion, and hepatitis. Deep jaundice and elevation of transaminases continues for several days, with aspartate aminotransferase (AST) elevated more than the level of alanine aminotransferase (ALT). Albuminuria is an important feature that differentiates YFV from other causes of viral hepatitis, and it can cause kidney failure.[13,18,19] Approximately 15 percent of patients develop severe disease, and approximately half of these will die. Death usually occurs within 7 to 10 days after the onset of symptoms.[13] Delirium, coma, and hypotension secondary to heart failure may occur before death.[20]

Dengue fever is distributed worldwide, especially in the tropics and subtropics. There is variation in the incubation period, but when the infection remains uncomplicated, the range can be from 3 to 14 days after the infective bite. However, if dengue fever progresses to dengue hemorrhagic fever or dengue shock syndrome (DSS), the incubation period is unknown.[19,21] The patient is acutely febrile for 3 to 5 days. Clinical manifestations widely vary and initially resemble flu-like symptoms including severe frontal headaches, myalgia, chills, rash, and retro-orbital pain. If the patient is young, anorexia, nausea, and vomiting differentiates dengue fever from other childhood febrile diseases. After the incubation period, the disease progresses to hemorrhagic manifestations, prostration, lumbar back pain, and abdominal tenderness. Localized clusters of petechiae might replace the preceding, fading rash. Shock can last 1 to 2 days, and DSS can result in an acute vascular leak.[19,21] Seventy-five percent of patients develop palpable hepatomegaly. Laboratory findings include elevated amylase levels, hypoalbuminemia, and elevated hematocrit.[19] Other laboratory examinations might show leukopenia, neutropenia, thrombocytopenia, and mildly elevated AST levels. With supportive treatment, patients experience remission within 2 to 3 days, with one percent mortality in well-provided centers. In underserved populations, however, mortality rates have reached 50 percent.[19]

OHF and KFD are found in Western Siberia and India, respectively. After a short incubation period of 3 to 8 days, patients exhibit a sudden-onset fever (>40°C), headache, severe muscle pain, cough, dehydration, GI problems, and papulovesicular lesions of the soft palate. Severe cases show nasal, enteric, or pulmonary hemorrhage.[13] Laboratory studies show leukopenia, thrombocytopenia, and albuminuria. A remission phase of 1 to 2 weeks is seen in some patients, and a subsequent severe illness is marked by meningoencephalitis. Fatality is 0.5 to 3 percent in OHF and 5 to 10 percent in KFD.[13] OHF frequently causes hearing loss, hair loss and behavioral/psychological difficulties associated with neurological conditions.

BUNYAVIRIDAE

CCHF is endemic in Africa, the Balkans, the Middle East, and Asian countries south of the 50th parallel north.[13,22,23] The incubation range following a tick bite is 1 to 3 days, with a maximum of 9 days, and the incubation period following contact with infected blood or tissues is usually 5 to 6 days, with a maximum of 13 days. Symptoms include sudden onset of fever, myalgia, dizziness, neck pain & stiffness, sore eyes & photophobia, nausea, and vomiting.[22] Sharp mood swings and mental status changes begin after a few days, with confusion and aggression progressing into lethargy, sleepiness and depression after 2 to 4 more days. Abdominal pain is usually present and may localize to the right upper quadrant, and hepatomegaly is often present. Hemorrhagic symptoms present with major coagulation dysfunction and thrombocytopenia; DIC may manifest on days 3 to 6 of illness. Mild cases

are marked by generalized petechial rash on the skin and mucosa, whereas severe cases are marked by ecchymosis, epistaxis, gastrointestinal bleeding, hematuria, and uterine bleeding. Patients might require multiple transfusions.[10,13,22,23] Liver function test results become elevated, and death can occur from liver failure and hepatorenal syndrome. Mortality approximates 30 percent and results from multiple organ system failure, blood loss, cerebral hemorrhage, pulmonary failure, or dehydration.[22] Patients who recover will typically begin to show improvement on day 9 or 10 after the onset of illness. Ribavirin has been shown to have some benefit for treatment in CCHF cases in oral and intravenous forms.

Hantavirus infection with the SNV typically has two main phases of clinical illness: initial and late phase. The initial phase is marked by a prodromal fever that is nonspecific and nearly impossible to distinguish as a hantavirus infection. It is thought that the initial symptoms may begin to appear between 1 to 5 weeks after exposure to fresh urine, droppings or saliva of infected rodents. The most frequently reported symptoms include fever, chills, fatigue, and muscle aches, especially in the large muscle groups, such as hips, thighs, back, and sometimes shoulders. In addition, patients may have headache, cough, nausea, abdominal pain, dizziness, and diarrhea. Physical examination may reveal tachypnea, tachycardia, wet rales, and abdominal tenderness. The late phase begins 4 to 10 days after the initial phase of illness. Progression of disease occurs precipitously and is characterized by coughing, shortness of breath, hypotensive shock, noncardiogenic pulmonary edema, and severe lactic acidosis. The clinical picture closely resembles adult respiratory distress syndrome (ARDS) but may also be easily confused with acute myocardial infarction or infections such as plague, leptospirosis, Legionnaire's disease, tularemia, coccidioidomycosis, histoplasmosis, or even severe acute respiratory syndrome (SARS). Patients become hypoxemic despite mechanical ventilation with 100 percent oxygen, and fatal pulmonary deterioration may ensue within days. The mortality rate in patients who progress to the second phase of HPS is approximately 38 percent.[24]

RVF has a geographic distribution in sub-Saharan Africa, Madagascar, and the Middle East.[23,25] The incubation period is 2 to 6 days, with most patients experiencing no symptoms or a mild febrile illness with liver abnormalities. Others display an influenza-like illness, with sudden onset of fever, headache, backache, and myalgia, and in some cases, development of neck stiffness, photophobia, and vomiting may occur. The symptoms of RVF usually last from 4-7 days, at which time the immune response becomes detectable with the appearance of immunoglobulin (IgM) and IgG antibodies. Less than three percent of patients develop severe disease, and complications include eye disease, meningoencephalitis, and hemorrhagic fever. The proportion of patients developing these complications is approximately 0.5 to 2 percent for eye disease and less than one percent for meningoencephalitis and hemorrhagic fever syndrome.[25] Eye diseases, including macular retinitis and vasculitis, can occur in up to two percent of patients and usually appear 1 to 3 weeks after the first symptoms, and patients may be afebrile. When the lesions are in the macula, some degree of permanent visual loss will result. Death in patients with only ocular disease is uncommon. Up to one percent of patients can also present with meningoencephalitis, beginning 1 to 3 weeks after the first symptoms. Mortality in patients with meningoencephalitis alone is rare.[25] Hemorrhagic symptoms caused by RVF occur 2 to 4 days after the onset of fever. Patients have severe liver disease, jaundice, and hemorrhagic phenomena, such as gingival and gastrointestinal bleeding, and purpuric rash. Those infected may remain viremic for up to 10 days. The case-fatality rate for patients developing hemorrhagic disease is high, approximately 50 percent.[13,23,25] Most fatalities occur in the severe hemorrhagic form of the disease. However, the overall fatality rate is less than one percent.[13,25]

Filoviridae

Marburg and Ebola are found in sub-Saharan Africa.[26,27] The incubation period is usually from 5 to 10 days, with a range of 2 to 21 days. Patients may present with a sudden onset of high fever, severe headache, backache, joint and muscle aches, sore throat, weakness conjunctivitis, diarrhea, vomiting, stomach pain, and a fine, maculopapular rash which develops several days into the illness. Marked mental status changes are often evident by day five. Bleeding from body orifices occurs in approximately one third of patients and is associated with high mortality.[28] Hemorrhagic manifestations develop within 5 to 7 days of the onset of symptoms, but the bilirubin level usually remains normal. Laboratory testing may show leukopenia and thrombocytopenia, as well as elevated prothrombin time, liver enzymes, and amylase. Abnormal electrocardiograms and reduced renal function occur in some patients.[13,25] Mortality ranges from 50 to 90 percent. Deaths usually occur during the second week of illness.[10,22]

Arenaviridae

Lassa fever has an incubation period of 3 to 16 days with a gradual onset of fever, chills, headache, myalgia, and sore throat.[23,29] Progression is more insidious than with Marburg or Ebola, and a purulent pharyngitis with white tonsillar patches is a distinguishing characteristic.[30] Retrosternal pain, relative bradycardia, albuminuria with casts, and an axillary petechial rash are seen.[13] Severe cases display shock, hemorrhage, pleural effusion, seizures, encephalopathy, and swelling of the face and neck. The hemorrhagic manifestations and the volume of blood loss are not enough to account for shock in these patients.[29] Eighth nerve deafness (unilateral or bilateral) is seen in 25 percent of those who recover. Only 50 percent will regain function over the next 1 to 3 months.[29] In severe cases, hair loss, ataxia, and loss of coordination may occur during convalescence.[13,29] Mortality rate is 15 to 20 percent in those hospitalized with severe disease.[29] Ribavarin has been used in Lassa fever cases with success, most often when given early in the illness.

New World arenaviruses have an incubation period ranging from 7 to 14 days.[13,21,29] The course is similar to Lassa fever with the notable absence of pharyngitis. Progression to hemorrhage with thrombocytopenia is common.[13,20] Half of patients with Machupo have intention tremor of tongue and hands, and 25 percent of patients will go on to delirium and convulsions.[13] Mortality is 10 to 20 percent, usually as a result of shock and renal failure.

LABORATORY DIAGNOSIS

Suspect VHF in patients with the constellation of symptoms described earlier and an appropriate travel or exposure history within 3 weeks of the onset of symptoms. **Diagnostic testing can only be done in BSL-4 laboratories.** Because of the inherent risk of handling specimens, the CDC requires notification before receiving specimens suspected of VHF. Consultation on preparation of specimens and shipping protocols is available 24 hours per day through the Special Pathogens Branch of the CDC.[4,31]

Confirmation of diagnosis requires virus isolation from blood or other body fluids, presence of specific IgM antibody, or demonstration of a fourfold increase in IgG titer between acute and convalescent serum specimens. YF antibodies can cross-react with other flaviviruses, including West Nile Virus,

dengue fever, and St. Louis encephalitis. Antibodies to the virus may take up to 2 weeks to become detectable; testing for specific antibodies is available through the CDC.

Antigen detection test by enzyme-linked immunosorbent assay (ELISA) is available, but it has limited value in early diagnosis. More rapid diagnostic modalities, such as antigen detection, virus genome detection using reverse transcriptase-polymerase chain reaction assay (RT-PCR), and immunohistochemical staining, are also available. The WHO has instituted mobile field laboratories in some African nations, enabling workers to diagnose Ebola within 24 hours.[28] Rapid testing ability decreases nosocomial infection rates by correctly identifying suspected cases early.

IMPLEMENTATION STRATEGIES FOR DIAGNOSIS AND TREATMENT

Strategies include identification of the suspect cases, which should be considered in patients (1) with a temperature 101°F or higher with abnormal bleeding and shock; (2) with a history of travel to endemic area; (3) who come in contact with a person with unexplained febrile illness with bleeding, or a person who died after an unexplained febrile illness; (4) who work in a laboratory or animal facility that handles hemorrhagic fever viruses; or (5) who are victims of bioterrorism. Initiate supportive treatment for all cases of VHF and include monitoring of electrolytes, replacement of fluid and blood, and correction of coagulopathy. Consultation on preparation of laboratory specimens and shipping protocols is available 24 hours per day through the Special Pathogens Branch of the CDC.[31] The possibility of bioterrorism must be considered in the event of a suspected VHF case(s) without a known exposure.[11,31,32] Patients should be managed per the infection prevention guidelines discussed later.

ANTIVIRAL THERAPY

Currently, there is no Food and Drug Administration-approved antiviral therapy for the treatment of VHF. However, ribavirin can reduce mortality after infection with Lassa fever and other Arenaviruses and Bunyaviruses.[33,34] Oral and intravenous (IV) ribavirin has been used with apparent benefit in the treatment of CCHF.[11,23] Ribavirin is not helpful in cases of VHF caused by flaviviruses or filoviruses.

Administer ribavirin immediately pending diagnostic confirmation. If infection with Arenaviruses or Bunya viruses is confirmed, complete a 10-day course of ribavirin. If infection with filoviruses or flaviviruses is confirmed or VHF is excluded, discontinue ribavirin. [52] For the most current guidance on treatment of VHF, refer to CDC or the WHO.

The efficacy of passive immunization is controversial. It has been shown to enhance viral replication in experimentally infected animals and has been used with good results in Argentine hemorrhagic fever.[11]

Monoclonal antibodies and human-derived products are currently under development. For Ebola, pre and post exposure prophylaxes have been achieved in animal models by passive transfer of neutralizing human monoclonal antibody, KZ52.[35]

Post exposure prophylaxis is hampered by the lack of effective vaccines and antiviral medications. The Working Group on Civilian Biodefense does ***not*** recommend prophylactic ribavirin in the absence of the described signs and symptoms of VHF. Persons potentially exposed to VHF agents should be placed under medical surveillance for 21 days. If there are any signs or symptoms of infection, preemptive treatment should be initiated promptly while pending confirmation and viral identification.[11]

General treatment for Ebola is supportive and includes IV therapy to balance electrolytes, maintain oxygen status and blood pressure and treat infections as they occur. Recovery after Ebola virus infection depends on the patient's immune response and having good supportive care. Some long-term complications have occurred for some patients after recovery. Ebola virus has been found in semen and other body fluids for extended periods of time. [51]

TRAVEL VACCINATION

A live-attenuated 17D vaccine exists for YFV and is the only licensed vaccine for any VHF. It is not useful for post exposure prophylaxis, because YFV has a short incubation period. Travelers who are more than 9 months old should receive the vaccine at least 10 days before arrival in endemic areas. Immunization is required before travel to some countries. Boosters are recommended every 10 years. There is an increased risk of post-vaccination encephalitis in patients aged less than 6 months. Information on the effects to the fetus is limited. An individual risk assessment should be performed on the pregnant woman if travel to endemic areas cannot be avoided.[36] Mothers should avoid nursing after vaccination. The vaccine should be avoided in persons with egg allergies or those with immunodeficiencies.[13] Two serious adverse reaction syndromes have been described: Yellow fever vaccine-associated viscerotropic disease (YEL-AVD) and Yellow fever vaccine-associated neurologic disease (YEL-AND). YEL-AVD is marked by multiple organ failure and disease patterns that mimic the wild type of the disease. Ten cases have been reported in the literature to date.[36] YEL-AND includes clinical syndromes such as meningoencephalitis, Guillain-Barre syndrome, acute disseminated encephalomyelitis, and some rare cases of bulbar and Bell palsies.

VACCINES IN DEVELOPMENT

Glycoprotein vaccines for Lassa fever have shown effectiveness in protecting primates, but human results are not available.[37] The Candid 1 vaccine is a live attenuated vaccine in development that has been shown to be efficacious in prevention of Argentine HF (Junin) in humans.[38] A formalin-inactivated RVF vaccine in development has been given to laboratory workers with subsequent increase in antibody titers. Three doses of inactivated vaccine were required to achieve a fourfold increase in antibody production.[39] A vaccine against dengue-2 virus involves the experimental inoculation of infectious DNA in rhesus macaques. Human trials of this technique and others are in progress with prospects for a recombinant human vaccine at least 5 to 10 years in the future.[40,41,42,43] An Ebola virus-like particle produced in insect cells using recombinant technology is being evaluated as a possible effective Ebola vaccine.[44] A live-attenuate recombinant vaccine against Marburg virus has shown encouraging results in animal studies with the potential of cross-protection across strains.[45]

Sierra Leone has a vaccine trial underway for Ebola, following the 2014 outbreak. The trial is called the Sierra Leone Trial to Introduce an Ebola Vaccine Trial (STRIVE). The vaccine, rVSV-ZEBOV, is being trialed in 5 districts of Sierra Leone. The vaccine, recombinant Vesicular Stomatitis Virus *Zaire ebolavirus* vaccine, should allow the host to develop Ebola antibodies due to replacing a gene in the vesicular stomatitis virus with a gene from the Ebola virus. This vaccine is aimed towards preventing the Ebola Zaire virus, which is the predominant strain of Ebola affecting the West African areas during the 2014 outbreak. [54]

INFECTION PREVENTION

Because of the lack of effective and licensed vaccines and drug therapy, preventing transmission of VHF relies on meticulous adherence to infection prevention measures. Immediately implement transmission-based precautions (Standard, contact, and droplet precautions at a minimum) including isolation of the suspected patient. In addition, notify (1) local and state health department, (2) infection prevention personnel, (3) laboratory personnel, and (4) an infectious disease specialist for consultation.

Prevention methods should include controlling rodent populations, not allowing rodents to enter living areas, removing their food and water sources, and ensuring appropriate and safe cleanup and disposal of nests and droppings. Additional prevention methods for HF viruses include the use of insect repellant, clothing that covers exposed skin, bed nets, window screens, and any other means to protect against insects and avoid being bitten.[4]

In the absence of a biologic attack, VHF is unlikely in patients who have traveled to affected countries/areas or who have onset of symptoms greater than 3 weeks after travel. Patients with travel-related fever are more likely to have other infections, such as malaria, hepatitis, and typhoid.

PREHOSPITAL PROCEDURES

Standard Precautions for blood-borne pathogens are all that is required when evaluating patients with suspected VHF undergoing prehospital evaluation with no additional isolation precautions necessary. If a patient has respiratory symptoms, the caregivers should use surgical masks with eye protection or face shields. If blood, emesis, urine, or feces are present, the patient should be managed as outlined in the hospitalized patient section.

The CDC developed guidelines for dealing with suspected Ebola patients during pre-hospital care after the outbreak in 2014. The guidance, “Identify, Isolate, and Inform” of suspected Ebola patients in the field, specifically any emergency medical technicians, paramedics, and any medical first responder, including law enforcement and fire service personnel. Particular emphasis is placed on assessment of travel history and symptoms to achieve early identification. PPE donning and doffing is an important piece of pre-hospital care and in the field as the situation is often in uncontrolled spaces and ambulance care is in a confined space. Appropriate disinfection of the ambulance and all contaminated items must be achieved with a US Environmental Protection Agency (EPA)-approved hospital grade disinfectant with a non-enveloped virus claim.

HOSPITALIZED PATIENTS

The majority of person-to-person and nosocomial transmissions of VHF occur through direct contact with infected blood and body fluids.[11,32,46,47,48,49,50] However, there is the possibility of spread of VHF by airborne means from aerosolized contaminated body fluids of the individual. The CDC recommends standard and droplet isolation for VHF during most patient care activities for suspected or confirmed VHF patients. For patients with suspected VHF who have prominent cough, vomiting, diarrhea, or hemorrhage, additional precautions must be taken.[46,49] Specifically, in the case of Ebola, CDC has published specific precautions for donning and doffing PPE, recommending the use of either a PAPR or disposable, NIOSH-certified N95 respirator in the case of a potentially aerosol-generating procedure. Refer to detailed guidance on Ebola:

Accessed at: **www.cdc.gov/vhf/ebola/healthcare-us/ppe/guidance.html**

A summary of transmission-based precautions recommended for management of a patient with VHF is noted here:

- In addition to standard precautions, patients should be placed on contact and droplet precautions for the duration of illness. A single patient room is highly recommended to prevent cross transmission between patients. Patients should wear a barrier mask until placed in a room and during transport to contain respiratory droplets.
- All persons entering the room should wear PPE as barrier protection: double gloves, with at least the outer pair of gloves being extended cuff and fluid-resistant or impermeable gown. All persons coming within 3 feet of the patient should also wear a surgical mask plus face shields, goggles or another form of eye protection. A trained observer should be used at all times to ensure PPE is donned and doffed correctly providing continuous coaching and prompting during the entire process.
- Additional barriers such as aprons and shoe and leg covers should be worn in situations in which contact with copious volumes of blood, feces, or vomit is anticipated. In the final stages of illness when viral load is greatest, hemorrhage is likely to occur and shoe and leg covers should always be worn preventively.
- Non-essential staff and visitors should be kept to a minimum, and should be required to wear appropriate PPE when entering the room. A log containing names, title, date, contact information, and time of visits of visitors and healthcare workers should be maintained.
- PPE should be carefully removed and disposed of in the patient room or anteroom, and soiled shoes should be disinfected.
- Standard Precautions for needle and sharp disposal should be followed to minimize the risk of percutaneous exposure.
- Surgical and obstetric procedures should be kept to a minimum. In the case where such a procedure is required, consult your state health department and the CDC for proper precautions.
- Hospitals may choose to institute airborne precautions, for patients with VHF who exhibit respiratory symptoms or in procedures with the production of aerosols (nebulized medication administration, endotracheal suctioning, bronchoscopy, positive pressure ventilation, or oscillatory ventilation). N-95 respirators will be required for these procedures.

If at any time during the doffing procedure there is a concern for contamination, or if a breach in PPE occurred at any moment during the patient care, the healthcare worker should report immediately to the doffing area to assess the exposure. The healthcare worker would then follow the facility's exposure management plan for appropriate occupational health follow up.

Extensive training for appropriate PPE donning and doffing for the HCW and trained observer should be conducted continuously to ensure policies and procedures are followed and cross-contamination does not occur. If a HCW is unable or unwilling to follow infection prevention guidelines, including donning and doffing of PPE, they should not provide care of patients with Ebola or any other VHF. The last step of the donning procedure should always be to have a partner verify that no areas of the body (skin or clothing) is exposed and that there are no breaches in PPE. Doffing must be completed in a methodical method as the type of PPE was designed and must be performed slowly under supervision to prevent contamination and exposure. The HCW must sanitize their hands between each step of the doffing process to ensure prevention of contamination.

Suitable solutions for disinfecting environmental surfaces include 0.5 percent sodium hypochlorite (1:100 daily dilution of household bleach) or an Environmental Protection Agency (EPA)-registered hospital disinfectant. Soaps and detergents can inactivate the viruses but should not be depended on for

disinfection.[49,50] Clothing and linens must be placed in labeled leak-proof bags and directly transported to the cleaning area. Linens can be autoclaved or washed in hot water with bleach and must be placed directly into the machine without sorting to avoid any potential exposures.[49,51] Disposable items used in patient care, such as suction containers and catheters, may be incinerated, decontaminated by autoclave, or immersed in an EPA-registered disinfectant, and then handled according to state and local regulations.

There is no evidence for transmission of hemorrhagic fever viruses to humans or animals through exposure to contaminated sewage; the risk of such transmission would be expected to be extremely low with sewage treatment procedures in use in the United States. As an added precaution, however, measures should be taken to eliminate or reduce the infectivity of bulk blood, suctioned fluids, secretions, and excretions before disposal by treatment with a decontaminating agent or autoclaving before disposal. [51]

LABORATORY

Laboratory staff exposure is a significant risk, and tests should be minimized to those absolutely necessary for patient care. Phlebotomists and laboratory staff should use PPE in accordance with Standard Precautions and the recommendations mentioned earlier. Specimens should be placed in sealed plastic bags and then transported directly to the specimen-handling area of the laboratory in clearly labeled, durable, and leak-proof containers. The specimen should remain in the custody of the designated person until testing is done. All specimens, including centrifugation and aliquots of serum, should be handled in at least a class 2 biological safety cabinet following BSL3 practices. Virus isolation should be done only in a BSL4 laboratory. Serum used in laboratory tests should be inactivated using 1 µg polyethylene glycol p-tert-octylphenyl ether (Triton X-100) per milliliter of serum.[49] This substance decreases viral titers but may not be 100 percent effective in inactivating virus. Automated systems should be used only if specimens have been inactivated first. The automated system should also be disinfected after use, as recommended by the manufacturer.

EXPOSURE

Any personnel with mucocutaneous or percutaneous exposures to blood, body fluids, secretions, or excretions, including sweat and tears, should immediately wash the affected skin area with soap and water. An antiseptic solution or handwashing product can be used although the efficacy has not been documented. Irrigate mucous membranes with large amounts of water or eyewash solution. Exposed persons should be evaluated as a contact and followed up.[49]

A contact is defined as any person exposed to the infected patient or their secretions, excretions, or tissue in the 3 weeks before the patient's onset of illness. [51] Contacts can be stratified into the level of risk: (1) casual contact, such as staying in the same hotel or flying on the same plane, does not constitute a significant exposure—special precautions are not needed; (2) close contacts, such as household contacts, patient caregivers, or personnel who have handled laboratory specimens without protective gear, will need to be placed under surveillance for 21 days—notify local health authorities; (3) high-risk contacts are those with mucous membrane, blood, or other body fluid exposure through kissing, sexual intercourse, needle stick, or other means—these individuals are placed under close surveillance and monitored for symptoms.

For contacts under surveillance, measure body temperature twice daily. If temperature of 38.3°C (101°F) or higher develops, or any symptoms of illness occur, the contact under surveillance is placed in isolation and given treatment for presumed VHF until proven otherwise.

Waste Management

The 2014 Ebola outbreak forced the CDC to evaluate the process for waste management when handling a patient with suspected or confirmed Ebola Virus. Any waste developed from a patient with suspected or confirmed Ebola Virus Disease is considered Category A infectious substance as regulated by DOT. If Ebola associated waste has been appropriately incinerated, autoclaved, or inactivated is not consider infectious waste. Local regulations should always be followed for infectious waste. [56]

AUTOPSY AND HANDLING OF THE HUMAN REMAINS[49]

Transmission of VHF can take place during post-mortem care. Handling bodies should be minimized, and the benefit versus the risk of autopsy must be carefully considered. The CDC should be contacted about further recommendations regarding autopsy and appropriate procedures for special circumstances. Aerosol formation should be avoided. Unnecessary handling of the body, such as embalming and cleaning of the body should be avoided. Do not remove any inserted medical devices from the body. The body should be placed in a sealed bag and cremated or buried promptly in a sealed metal casket. [57]

Conclusions

Understanding and proper recognition of VHF are of vital importance because of the high morbidity, mortality, and risk of hospital spread, and the potential as a bioterrorism agent. Early treatment with ribavirin can improve survival with some forms of VHF, and, in these cases, treatment should be initiated while awaiting virus confirmation. International travel has led to an increased risk of these diseases spreading from endemic areas, and recent cases have been imported to Europe and the United States from endemic countries. The knowledge of pathogenesis and clinical presentations should help clinicians identify suspected cases. Appropriate isolation, reporting, preemptive treatment, and confirmation of diagnosis must be initiated for the suspected index cases. The exact pathogenesis and modes of transmission are currently under investigation. Vaccinations, antiviral treatments, and prophylactic therapies are all in development.

Future Trends

Mechanisms of disease transmission of many of these agents remain incompletely understood. The increase in travel and potential bioterrorism threat make developing new diagnostic techniques, vaccines, and drug therapies urgent. Vaccines to Junin (Argentine HF) and RVF are available as investigational new drugs. A vaccine to KFD is under development. Development of new antiviral therapies for VHF is being pursued, as well as development of treatment protocols for pediatric cases. There are several candidate vaccines in trial phases for dengue/sever dengue.

International Perspective

Globalization makes the spread of VHF out of endemic areas inevitable, and an understanding of the evolving endemic zones allows for a better risk assessment for patients planning on traveling. For YF, immunization is required before entering some countries. Information regarding diseases and outbreaks, as well as the recommended and required vaccinations, is available at the CDC home page for traveler's health. A guideline from the CDC on infection control for VHF in the African healthcare setting is available for infection preventionists working in African settings. See "Supplemental Resources" at the end of this chapter.

Hemorrhagic fever viruses pose a valid threat as biological weapons. The high morbidity and mortality, low inoculum needed for environmental stability, and feasibility of large-scale production all serve to make VHFs possible bioterrorism weapons. Some countries are suspected of having these agents, and other countries have used these agents in the past.[11]

It is vitally important to understand the perceptions of the public. A single case will promptly draw public attention and increase fear and anxiety. In the era of borderless communication, a local outbreak can transform the national audiences into "armchair victims." This phenomenon is called "vicarious rehearsal." It may produce multiple negative behaviors, such as demand for unneeded treatment, multiple unexplained physical symptoms, unreasonable travel restrictions, self-destructive behavior, and reliance on media rumors.

Healthcare personnel and authorities should avoid over-reassurance, but should repeatedly state concern and keep the public factually up to date. Physicians and public health officials need to keep the options of response open and prepare the public for death and grief as well as unexpected occurrences.

Abstract

The purpose of this chapter is to review the epidemiology, description, pathogenesis, clinical features, diagnosis, treatment, and prevention of viral Hepatitis A–E. Viral Hepatitis A and E are non-bloodborne, fecal-oral transmitted viruses with no chronic state. Viral Hepatitis B–D are bloodborne viruses with chronic carrier states. Serological markers have been developed for Hepatitis A–E. Vaccinations are very effective for Hepatitis A and B but not for the other viruses. Postexposure passive prophylaxis with immunoglobulin is effective in both Hepatitis A and B but not in Hepatitis C–E. Standard bloodborne infectious disease precautions should be used in active Hepatitis B–D.

Key Concepts

- Currently, five hepatotropic viruses, A, B, C, D, and E are responsible for viral hepatitis in the United States. Hepatitis A, Hepatitis B, and Hepatitis C are the most common.
- All five can cause acute inflammation of the liver. Infections with Hepatitis A and Hepatitis E are usually self-limited. Infections with Hepatitis B, Hepatitis C, and Hepatitis D can lead to chronic lifelong infections.
- Chronic Hepatitis B, Hepatitis C, and Hepatitis D can lead to cirrhosis, liver failure, and hepatocellular carcinoma.
- Hepatitis A and Hepatitis E are transmitted via contaminated food and water. Hepatitis B, Hepatitis C, and Hepatitis D are transmitted by blood, sexual contact, exposure to contaminated equipment, and

from mother to infant during childbirth.

- Breaches in infection prevention practices may lead to increased risk and exposure to the hepatitis viruses.
- Vaccines are available for Hepatitis A and Hepatitis B. No vaccines are available for Hepatitis C, Hepatitis D, or Hepatitis E, and prevention is the key.

Background

This chapter includes a review of viral hepatitides with special mention of new advances in these viruses since the last edition of this textbook. Five hepatotropic viruses known to cause hepatitis have been described and have been named Hepatitis A, B, C, D, and E in historical order of their recognition. Worldwide, cases of hepatitis presumably caused by viruses other than these five also occur. Hepatitis A virus (HAV) and Hepatitis E virus (HEV) are transmitted principally by the fecal-oral route and are occasionally a healthcare infection prevention issue. Hepatitis B virus (HBV), Hepatitis C virus (HCV), and Hepatitis D virus (HDV) are bloodborne pathogens and pose a risk of healthcare-associated transmission or occupational exposure for healthcare personnel (HCP). Critical features of these types of viral hepatitis are summarized in Table 97-1. Standard Precautions, which encompass both universal precautions and body substance isolation, are appropriate for prevention and spread of all types of viral hepatitis in the healthcare environment.[1,2,3]

Patients and employees in U.S. healthcare facilities are at risk for transmission of hepatitis because of breaches in infection prevention procedures and exposures to asymptomatic carriers, contaminated needles and equipment, and unsafe needle practices. Understanding the epidemiology and pathogenesis of viral hepatitis can help in the development of prevention strategies to protect patients, employees, and the public. Transmission knowledge of hepatitis is also important for compliance with Occupational Safety & Health Administration (OSHA) bloodborne pathogens regulations, communicable disease reporting, and clinical practice review. The recent outbreaks of HCV in U.S. ambulatory centers highlight the need for infection prevention strategies and focus across the continuum of care.[4,5]

Table 97-1 Epidemiological and Clinical Features of Viral Hepatitis

Virus	HAV	HBV	HCV	HDV	HEV

Basic Principles

Viruses that infect hepatocytes are considered hepatotropic viruses. These viruses may also infect other cells, but the clinical disease associated with these viruses is characterized by a clinical syndrome consisting of malaise, elevated transaminases, inflammatory infiltrate within the liver, hepatocyte injury, and death. The clinical syndrome is similar among Hepatitis A–E, but the epidemiology, treatment, and prevention are different. The infection prevention of each of the viral hepatitides contains specific recommendations.

Hepatitis A

EPIDEMIOLOGY

Description

HAV is assigned its own genus, *Hepatovirus,*in the family Picornaviridae. HAV is a nonenveloped, 27-nm single-stranded RNA virus that can be found by electron microscopy in the feces of persons with this infection. Humans and primates are the only known natural hosts for HAV. Replication of HAV occurs in the hepatocytes, but the virus is not directly cytopathic.[1,3]

Incidence

HAV is highly contagious but rates in the United States have declined by 95 percent since HAV vaccine first became available in 1995. In 2010, 1,670 acute symptomatic cases of Hepatitis A were reported; the incidence was 0.6/100,000, the lowest rate ever recorded. The estimated number of new infections was 17,000 when adjusted for asymptomatic infection and underreporting.[6]

The incidence of HAV in the United States used to vary dramatically by ethnicity and geography, but this has largely disappeared in the HAV vaccine era. Rates have dropped 99 percent in American Indians and Alaskan Natives to rates now below the U.S. rate. Rates in Hispanics have decreased substantially as well, but are still twice as high as non-Hispanics. HAV rates before 1997 were much higher in the western and southwestern regions, but this regional variation no longer exists.[7]

The incidence of HAV varies considerably worldwide, with annual rates depending on the endemicity level of the country. Children from countries where HAV is highly endemic have a high seroprevalence (90 percent) and, because symptoms are limited in young children and adolescents and adults retain lifelong immunity, epidemics are uncommon. In transitional economies of the developing world where sanitation and public infrastructure are improving, fewer children are exposed to Hepatitis A, which in turn actually leads to larger outbreaks due to lower population level immunity in adolescents and adults.[8]

Transmission

HAV is transmitted principally by the fecal-oral route, with the highest level of virus in the feces found in the 2 weeks prior to onset of jaundice or liver enzyme increase.[9]This is also the period of highest infectivity.[10]Transmission is facilitated by intimate personal contact (household, sexual, etc.), poor hygiene, unsanitary conditions, or contaminated water, milk, or food, especially raw shellfish. Additional risk factors include childcare exposure (children, parents, or attendants), intravenous (IV) drug use, travel to an endemic area, chronic institutionalization, men who have sex with men (MSM), and occupation (e.g., sewage worker, pediatric nurse). HAV is rarely transmitted by blood or blood products (e.g., clotting factor concentrates) as a consequence of transient viremia in asymptomatic donors.

Pathogenesis

Infection with HAV occurs in the gastrointestinal tract. HAV is transiently detectable in blood as early as 4 weeks before symptoms. HAV is detectable in feces 2 to 4 weeks before and 1 to 3 weeks following the onset of jaundice. Infected neonates may shed HAV in feces for months. There is no chronic HAV carrier state. HAV replicates in cytoplasm of hepatocytes, and then is shed in bile, which results in high

titer of infectious HAV in feces. Disease occurs as a result of host immune response, which causes hepatocyte injury. Development of antibodies to HAV confers lifelong immunity.[1,3]

CLINICAL FEATURES

Infection is unapparent in 70 percent of young children under 6 years of age. In older children or adults, infection is typically symptomatic, with jaundice occurring in more than 70 percent of patients. Incubation period averages 4 weeks (range, 15–50 days) and may depend on inoculum size. Prodromal (preicteric) symptoms are nonspecific, including malaise, fatigue, anorexia, nausea, vomiting, abdominal discomfort, arthralgia, myalgia, and fever. This phase lasts 1 to 2 weeks. The icteric phase is notable for jaundice, dark urine, pale colored stools, pruritus, and anorexia, but resolution of prodromal symptoms lasts 1 to 4 weeks. Alanine aminotransferase (ALT) and other hepatocellular enzymes and bilirubin levels rise and then generally recover completely over 2 weeks to 6 months.[1,3,11,12]

LABORATORY DIAGNOSIS

Clinical features of acute hepatitis are not specific for HAV infection, so serological diagnosis is necessary (Figure 97-1). Immunoglobulin M antibodies to HAV (IgM anti-HAV) are used to detect acute HAV infection, are detectable within 3 weeks of exposure, and are present at the onset of jaundice. Titer declines over 4 to 6 weeks and is usually not detectable after 6 to 12 months. Immunoglobulin G anti-HAV (IgG anti-HAV) is also detectable at onset of jaundice and remains positive lifelong, indicating immunity to HAV.[1,3]

View Image

TREATMENT

Supportive care (e.g., fluids and nutrition) is the only known management for acute Hepatitis A. Liver transplantation should be considered in the course of fulminant hepatic failure.[1,3]

PREVENTION

Public health and personal hygiene measures, including hand washing or hand sanitizer, may effectively interrupt further transmission. Risk of transmission of HAV is transient and occurs during the prodrome. Standard Precautions are appropriate to prevent healthcare-associated transmission in most instances. With diapered or incontinent patients, the addition of Contact Precautions is recommended. Postexposure prophylaxis should be considered in instances such as household or sexual contacts or in outbreak situations such as common source exposure in an infected food handler or a case of HAV in a childcare center. HAV vaccine is recommended for unvaccinated adults aged 40 or younger with recent (within 2 weeks) exposure to HAV. For persons over 40 with recent (within 2 weeks) exposure to HAV, immune globulin (Ig) is preferred over vaccine.[13]A dose of 0.02 mL/kg intramuscular (IM) protects for up

to 3 months. The local health department should be notified immediately about a case of Hepatitis A so that tracing and prophylaxis of contacts can be initiated promptly. For international travelers going to endemic regions, HAV vaccine should be given prior to departure. For those over 40, a higher dose (0.06 mL/kg IM) of Ig can be considered as an alternative to HAV vaccine prior to travel,[13] though this is not routinely practiced.

Active immunization with either licensed single antigen HAV vaccine (HAVRIX, manufactured by GlaxoSmithKline; VAQTA, manufactured by Merck & Co., Whitehouse Station, NJ) or combination TWINRIX (manufactured by GlaxoSmithKline, Rixensart, Belgium), which contains both HAV (in a lower dosage) and HBV antigens, is generally safe and effective. More than 95 percent of adults generate protective antibodies within a month of HAV vaccination. A booster is recommended at 6 to 12 months. There are different formulations for children and adults. In addition to the instances of postexposure prophylaxis and international travel, immunization should be offered to select adult populations that are either at high risk of acquiring HAV or at risk for fulminant presentation once disease is acquired. These groups include patients with chronic liver disease, IV drug users, MSM, persons who receive clotting factor concentrates, persons who work with HAV in experimental lab settings (not routine medical laboratories), and food handlers when health authorities or private employers determine vaccination to be appropriate. HAV vaccine is recommended for all children at age 1 year (12–23 months) with a second dose spaced 6 months apart and all previously unvaccinated children and adolescents age 2 years and older who live in a state, county, or community with a routine vaccination program already in place for children aged 2 years and older.[13]

Solvent-detergent treatment of clotting factor concentrates has failed to prevent transmission of HAV by these products. Heat screening of plasma-derived clotting factors inactivates HAV and other viruses.[1,2,3,11,12,14,15,16,17]

Hepatitis B

EPIDEMIOLOGY

Description

HBV is a small DNA virus in the family Hepadnaviridae. HBV utilizes its own reverse transcriptase for replication. HBV virus overproduces envelope proteins (e.g., Hepatitis B surface antigen [HBsAg]), which can be detected by testing of serum. Nucleocapsid core antigen (HBcAg) and the e antigen (HBeAg, a marker for viral replication and infectivity) are also generated. Detection of these components or host antibodies to HBsAg, HbeAg, or HBcAg are used to diagnose and monitor acute and chronic HBV.

Historically, HBV was the most common bloodborne pathogen with risk for HCP. The incidence of HBV among HCP dramatically fell in the 1990s because of preventive measures mandated by the OSHA Bloodborne Pathogen Rule of 1991.[1,2,3,14,16,18,19,20,21,22,23,24,25,26,27,28]

Incidence

In 2009, an estimated 38,000 persons in the United States were newly infected with HBV. This is a decline of approximately 82 percent since 1991, when the United States instituted a national strategy to eliminate HBV infection with the routine vaccination of children was first recommended.[29] The rates of HBV in HCP was at one time higher than that of the general population due to bloodborne exposure

risk.[30]However, there was a 95 percent decline from 1983 to 1995 among HCP as a result of behavioral changes and widespread HBV immunization.[31]

In the United States in 2006, a total of 4,713 acute, symptomatic cases of HBV were reported nationwide; 40 percent were hospitalized and 0.8 percent died. The proportion of persons hospitalized for HBV increased with age, from 12 percent among children under age 15 to 51 percent among persons over 60.[32]It is estimated that chronic HBV leads to 4,000 deaths per year from cirrhosis and 800 from hepatocellular carcinoma.[21,28]

Prevalence

Worldwide, 240 million people are chronic HBV carriers. Of carriers, many develop serious liver disease resulting in 600,000 deaths per year. The highest prevalence is in subSaharan Africa and East Asia, where 5 to 10 percent of the population are HBsAg positive. High rates of chronic infections are also found in the Amazon and the southern parts of eastern and central Europe. In the Middle East and Indian subcontinent, an estimated 2 to 5 percent of the general population is chronically infected. Less than 1 percent of the population in Western Europe and North America is chronically infected.[33]

The estimated prevalence of chronic Hepatitis B in the United States, according to analysis based on results of the NHANES survey, was 730,000.[34]This estimate is felt to be low, as high-risk groups such as foreign-born individuals and prison populations are underrepresented in the survey. A recent study that used modeling based on prevalence rates of chronic Hepatitis B in 98 countries multiplied by immigration data from those countries estimated the prevalence of foreign-born individuals with chronic Hepatitis B in the United States at 1.3 million in 2009.[35]The risk for chronic infection varies according to the age at infection and is greatest among young children. Approximately 90 percent of infants and 25 to 50 percent of children aged 1 to 5 years will remain chronically infected with HBV. By contrast, approximately 95 percent of adults recover completely from HBV infection and do not become chronically infected.

Transmission

HBV is parenterally transmitted through blood or blood products, sexual contact, or perinatal exposure of an infant. HBeAg positivity is associated with increasing infectivity. In low-prevalence areas such as the United States, HBV is principally transmitted by sexual contact or IV drug use and is less efficiently transmitted by contact with saliva or mucosal surfaces. From 20 to 30 percent of cases in the United States have no known risk factors or route of infection. In nations where HBV is more prevalent, vertical perinatal transmission from HBsAg-positive mother to child or horizontal transmission among young children is more common. HBV is detectable in various body fluids that may be infectious, including blood, semen, vaginal secretions, saliva, tears, cerebrospinal fluid (CSF), ascites, and other serous fluids. Infectivity is enhanced by high virus titer or HBeAg positivity in serum of source patient. No arthropod-borne, waterborne, or airborne transmission is known.

Pathogenesis

Host immune response is more important than HBV cytopathic effects on hepatocytes. During acute HBV, cytotoxic T-lymphocytes initiate liver injury, followed by antibody-mediated immunity. Mutant HBV strains may escape otherwise protective immunity or cause more severe or chronic infection. Immaturity of T-cell immune system (e.g., children, immunosuppressed hosts) may permit chronic HBV infection. Development of surface antibody (anti-HBs) and clearance of HBsAg denote resolution of HBV disease,

leading to durable protection from reinfection.[1,3,23,26] The HBV circular DNA does not need to integrate into host DNA to complete the viral life cycle, but when it does, it may act as a mutagen that drives the development of hepatocellular carcinoma.

CLINICAL FEATURES

The incubation period ranges from 30 to 180 days (mean, 75 days). Prodromal urticarial rash, arthritis, and fever occur in 5 to 10 percent of adults. Neonates or young children are usually asymptomatic. Acute HBV is more insidious and prolonged than HAV. Fulminant hepatic failure is rare but can be fatal without liver transplantation. Symptoms resemble HAV. In acute HBV (Figure 97-2), HBsAg, HBeAg, and HBV DNA are detectable in serum 2 to 7 weeks before onset of symptoms. When symptoms occur, immunoglobulin M anti-HBV core (IgM anti-HBc) and ALT, aspartate aminotransferase (AST), and bilirubin levels all rise. ALT levels generally exceed AST and are usually elevated 10- to 20-fold from normal. Bilirubin elevations vary with severity. Prolonged prothrombin time (international normalized ratio [INR] ≥ 1.5) or hypoalbuminemia imply severe hepatic injury and may portend fulminant hepatic failure. Acute HBV resolves slowly (weeks to months) following detection of immunoglobulin G anti-HBc (IgG anti-HBc), anti-HBe, and anti-HBs, and disappearance of HBeAg and HBsAg. IgM anti-HBc may persist for months then disappear.

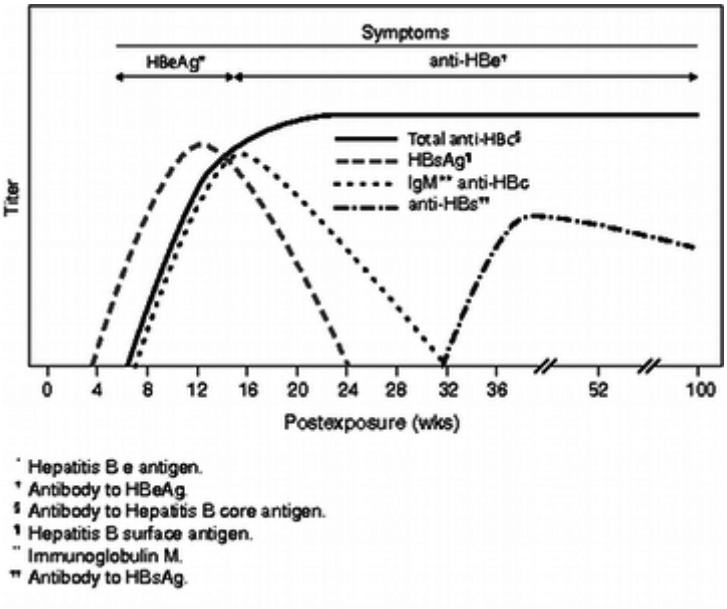

Figure 97-2.

Serological course of acute Hepatitis B virus infection with recovery. (From Weinbaum CM, Williams I, Mast EE, et al. Recommendations for identification and public health management of persons with chronic hepatitis B virus infection. *MMWR Recomm Rep*2008 Sep 19;57(RR-8):1–20.)

View Image

In chronic hepatitis (Figure 97-3), HBsAg, HBeAg, and HBV DNA are detected for more than 6 months, and ALT and AST levels fall but do not always return to normal. These persons remain infectious for others; those with HBeAg are highly infectious and are at greatest risk of developing cirrhosis or hepatocellular carcinoma. Persons who have human immunodeficiency virus (HIV) or other forms of immunosuppression (e.g., dialysis patients) and who acquire HBV infection are more likely to develop chronic HBV and associated liver complications than are those without these comorbid conditions.[1,3,23,36]

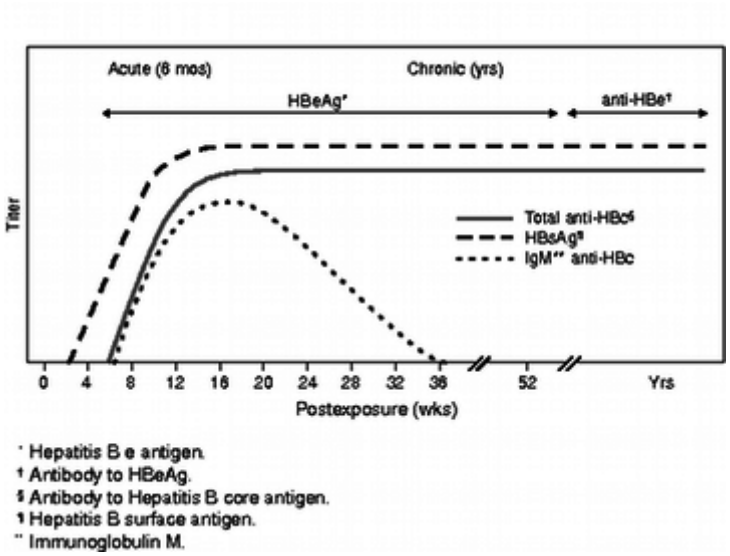

Figure 97-3.

Progress to chronic Hepatitis B infection: serological course.

View Image

LABORATORY DIAGNOSIS

In prodromal or preicteric HBV disease, HBsAg, HBeAg, and HBV DNA are detectable in serum (see Figure 97-2), with HBsAg becoming positive 1 to 10 weeks after an exposure and before the onset of symptoms. Finding HBeAg and high concentration of HBV DNA signify high rates of HBV replication and

heightened infectivity. With onset of symptoms, rise in levels of aminotransferases and bilirubin, IgM anti-HBc becomes positive. This is the ideal test to determine whether an acute hepatitis is due to Hepatitis B, since the titer rises with onset of symptoms and falls below detectable levels after several months, so it is not positive in those with chronic Hepatitis B. As acute illness wanes over a period of weeks, aminotransferases and other biochemical monitors improve. HBeAg, HBV DNA, and HBsAg may disappear. IgG anti-HBc, anti-HBe, and anti-HBs are detectable.

In chronic HBV, biochemical abnormalities may persist, and a positive serum test for HBsAg for more than 6 months is diagnostic of chronic Hepatitis B (see Figure 97-3). IgG anti-HBc remains detectable, but IgM anti-HBc declines. Eventually HBV DNA and HBeAg may disappear, and this signifies an asymptomatic carrier. In active chronic infection, transaminases and HBV DNA remain elevated. These patients can either be HBeAg positive or HBeAg negative. HBeAg positive patients can spontaneously convert to anti-HBe, typically with an acute rise in transaminases, then return to normal, along with a fall in HBV DNA and improved liver inflammation level. IgG anti-HBc persists for life in both chronic active HBV and in persons who have cleared an acute infection. Persons with chronic HBV (particularly HBeAg positive and HBV DNA positive) remain infectious for others.[1,3,23]

TREATMENT

For acute HBV, only supportive care is indicated, and hepatotoxins such as acetominaphen should be avoided. In fulminant HBV, liver transplantation is often required. In chronic HBV, treatment options include pegylated interferon alfa-2a, lamivudine, adefovir, entecavir, telbivudine, and tenofovir. Pegylated interferon is a subcutaneous injection and efficacy is dependant on host immune response. The side effects of pegylated interferon include flulike symptoms, marrow suppression, depression, and autoimmune thyroiditis; close medical supervision and laboratory monitoring are required. The other therapies are all oral agents that generally have an acceptable side effect profile even after extended use, but because adefovir and tenofovir may cause nephrotoxic effects, periodic monitoring of renal function during therapy is advisable.[37]Other agents, such as lamivudine, can cause viral resistance when used as monotherapy. Entecavir also inhibits HIV replication and can cause HIV resistance, so it should not be used in HIV/HBV co-infected patients who are not on HIV antiretroviral therapy.

Liver transplantation is considered for end-stage chronic HBV complications. Hepatitis B immune globulin (HBIG) with lamivudine prophylaxis improves liver transplant outcome, with reinfection rates as low as 10 percent.[38]Patients with chronic HBV who are susceptible to HAV benefit from HAV vaccine.[1,2,3,23,25,26,39]

PREVENTION

Standard Precautions should be used to prevent exposure of HCP to blood or body fluids of HBsAg-positive patients. Counseling should be provided to prevent exposure of sexual or household contacts while the patient has detectable HBsAg. The risk to nonimmune HCP of acquiring HBV after a sharps

injury exposure to an HBsAg-positive patient is 6 to 30 percent (the highest risk is if the source patient is HBeAg-positive), so postexposure prophylaxis of HCP with HBIG and vaccine is recommended.[1,2,3,14,15,16,17,20,21,22,23,24,25'36]

Active Immunization

Routine vaccinations are recommended for HCP prior to starting employment.

Hepatitis B Vaccine

HBV vaccine is available as a single-antigen formulation and also in fixed combination with other vaccines. Two single-antigen recombinant, thimerisol-free vaccines are available in the United States: Recombivax HB (Merck & Co.) and Engerix-B (GlaxoSmithKline Biologicals). Of the three licensed combination vaccines, one (Twinrix [GlaxoSmithKline Biologicals]) is used for vaccination of adults and two (Comvax [Merck & Co.] and Pediarix [GlaxoSmithKline Biologicals]) are used for vaccination of infants and young children. Twinrix contains recombinant HBsAg and inactivated Hepatitis A virus. Comvax contains recombinant HBsAg and *Haemophilus influenzae*type b (Hib) polyribosylribitol phosphate conjugated to *Neisseria meningitidis*outer membrane protein complex. Pediarix contains recombinant HBsAg, diphtheria, and tetanus toxoids and acellular pertussis adsorbed (DTaP), and inactivated poliovirus (IPV).[40]

Seroconversion with detection of protective anti-HBs (>10 mIU/mL) occurs in more than 95 percent of healthy recipients. Risk factors for poor responses to HBV vaccination include age over 40 years, hemodialysis, HIV infection, tobacco smoking, improper vaccine storage, subcutaneous vaccine delivery, and an accelerated vaccine schedule. Persons who are HBsAg positive will also not respond to HBV vaccine. Thus, it could be reasonable to test a nonresponder for HBsAg carriage. Dialysis patients and immunocompromised hosts respond less predictably and should receive a higher dose (40 µg) at each interval. Serum levels of anti-HBs decline slowly over several years after a successful vaccine series. However, routine testing for anti-HBs and routine booster immunization are not recommended except in persons at risk for a poor antibody response (e.g., neonates or immunosuppressed hosts) and at high risk of ongoing exposure.

Pre-immunization testing for HBV markers is not cost effective except in certain populations. If, however, testing for any marker is positive, HBV vaccine is not useful. HBV vaccine is recommended as a routine childhood immunization series beginning in infancy. Despite immunization programs targeted at high-risk groups, as well as recommendations for universal childhood immunization, compliance with HBV vaccination in the general population has been disappointing in the United States and unaffordable in the developing world. HBV vaccination is recommended for persons in certain high-risk groups, including people with multiple sexual partners, sexual partners or household contacts of HBsAg-positive people, MSM, IV drug users, long-term travelers to regions with endemic HBV (see **118. Travel Health**), persons with risk of exposure to blood or body fluids as a result of their occupation, clients and staff at institutions for the developmentally disabled, patients with chronic renal failure and dialysis, patients receiving clotting factor therapy, and inmates at long-term correctional facilities.[40]

Pregnancy is not a contraindication for HBV immunization. HCP with risk of ongoing exposure to body fluids should be tested 1 to 2 months after their third dose of HBV vaccine to determine serological response (anti-HBs). This result is useful in planning for possible future prophylaxis. HCP who do not respond to the primary vaccine series (anti-HBs ≥10 mIU/mL) should complete a second full series and be tested for HBsAg.[41]HBsAg-negative HCP who do not respond to a second vaccine series should

subsequently receive HBIG for any known or probable parenteral or mucosal exposure to HBsAg-positive blood or body fluids. Vaccinated HCP whose anti-HBs level has never been tested should be tested for anti-HBs immediately after an occupational exposure to HBV. If the anti-HBs level is adequate, no HBV prophylaxis is necessary. If the anti-HBs level is less than 10 mIU/mL, a single dose of HBIG and a booster dose of HBV vaccine are given. HBIG is not recommended when the HBsAg serostatus of the source patient is unknown or not tested, unless the source patient is high risk for HBV.[41]

HCP who are HBsAg positive require close follow-up. Recent guidelines from the U.S. Centers for Disease Control and Prevention (CDC) provide updated guidance for the management of HBV chronically infected healthcare providers.[42]It is recommended that HBV viral load be monitored and that those with viral levels more than 1,000 IU/mL should not perform exposure-prone procedures such as certain surgeries. The U.S. incidence of HBV infection in hemodialysis units has declined by 95 percent since the 1980s as a result of the use of Universal Precautions and HBV vaccination of patients and HCP in these units.[43]Besides these measures, hemodialysis-specific recommendations include (1) patients should be tested annually for anti-HBs and revaccinated if they are no longer immune (dialysis dose is 40 µg); (2) instruments, medications, and supplies for these patients should not be shared; (3) routine cleaning and disinfection procedures should be followed, with separate clean and contaminated areas; and (4) blood and body fluid specimens should be handled with gloved hands and kept away from areas used for medications or supplies.

Passive Immunization

HBIG is indicated as postexposure prophylaxis for persons not already immune to HBV when they have percutaneous or mucosal exposure to blood or body fluids of a source person testing positively for HBsAg. The dose is 0.06 mL/kg IM as soon as possible after exposure but not delayed more than 7 days. This should be repeated at 30 days if the HBV vaccine series was not begun. HBIG is also recommended for recent sexual contacts of all HBV-infected persons who are not HBV immunized[44]and infants born to mothers who are HBsAg positive.[45]Universal HBsAg testing of pregnant women is recommended to detect all candidate infants for HBIG programs. In each circumstance in which HBIG is used, HBV vaccine is also simultaneously indicated. Combined HBV vaccination and HBIG immunotherapy of newborns at risk can prevent more than 90 percent of prenatally transmitted HBV.[46]

The dose of HBIG for neonates is 0.06 mL/kg IM within 12 hours of birth.

Hepatitis C

TRENDS

HCV was initially known as non-A, non-B viral hepatitis, which was often seen in the posttransfusion setting. After discovery of the viral antigens, the virus was named Hepatitis C. Like HBV, HCV is a common cause of cirrhosis and hepatocellular carcinoma. Unlike HAV and HBV, though, no vaccine exists. Treatment for HCV is entering a new era with the burgeoning availability of direct antiviral agents.

EPIDEMIOLOGY

Description

HCV is a single-stranded RNA virus in its own genus in the family Flaviviridae. Following detection of its RNA in serum in 1989, the genome of HCV has been cloned, but the virus has not been propagated in vitro. HCV is found as multiple genotypes and genetic subtypes that differ in their geographic distribution. In the United States, genotype 1 is most common, followed by genotypes 2, 3, and 4. This genetic variation is a major obstacle to development of a vaccine to prevent HCV infection.[1,3,16,21,25,27,47,48,49,50,51,52,53,54,55]

Incidence

The third National Health and Nutrition Examination Survey (NHANES III), spanning 1988 to 1994, estimated that 1.8 percent (3.9 million) of the U.S. population has been infected with HCV. The annual incidence of acute HCV infections decreased from 180,000 in the mid-1980s to an estimated 19,000 cases in 2005. HCV causes approximately 20 percent of community-acquired acute viral hepatitis, with incidence declining since the late 1980s. Of these HCV infections, 85 percent become chronic. Cirrhosis occurs in 20 percent of patients with chronic HCV, usually occurring after 20 years, whereas hepatocellular carcinoma (HCC) occurs in only 5 percent, usually after 30 years. HCC results in 8,000 to 10,000 deaths per year. HCV is the most common infectious cause of chronic hepatitis, cirrhosis, and HCC in the United States and is the most common indication for liver transplantation.[41,47,54,55,43,56,57]

Prevalence

The World Health Organization estimates that the global prevalence of HCV infection is 3 percent (approximately 170 million HCV-infected persons) worldwide. The highest prevalence is in the Middle East and North Africa, where 7 to 26 percent of some populations are HCV carriers. In the United States, approximately 3.2 million people have HCV infection.

Infection is most prevalent among those born during 1945 to 1965, the majority of whom were likely infected during the 1970s and 1980s when rates were highest. As a result of the high prevalence in this age group, the CDC now recommends that all adults born between 1945 and 1965 be screened at least once for HCV, regardless of other risk factors.[58]In the United States, groups with a high prevalence of HCV infection include IV drug users (60 percent of new cases), persons with multiple sexual partners, HIV patients, hemophiliacs receiving clotting factors prior to 1987, and recipients of blood product transfusions or organ transplants prior to 1992. Other groups at risk are hemodialysis patients, HCP (1 percent prevalence), infants born to HCV-infected mothers, nasal cocaine users, and persons with tattoos and multiple body piercings. In one U.S. inner city hospital emergency department that served a population of drug users, 18 percent of patients were HCV positive. Surveys suggest that approximately one-third of U.S. prison inmates carry HCV. In about 5 percent of all HCV infections, no risk factor can be identified.[47,55,43]As a result of screening for risk factors, only 0.6 percent of blood donors are HCV positive; these are detected by serological testing and excluded from donation.

Transmission

HCV is efficiently transmitted parenterally by blood injection (injecting drug users), organ transplantation, or transfusion of HCV-infected blood or blood products (including clotting factors and intravenous immunoglobulin). Prior to testing blood and blood products in the early 1990s, risk of HCV transmission was 0.19 percent per unit transfused. Since screening was implemented, the risk is only 0.001 percent per unit. Since 1994, no transfusion-associated HCV transmission has been detected. Nonetheless, 5 to 10 percent of HCV cases are transfusion associated. Risk of transmission of HCV from an infected patient to HCP as a result of a needlestick is 1.8 percent. There is a high prevalence of HCV among

hemodialysis patients.[45]HCV has been transmitted from surgeon to patient and when safe medical injection equipment or solution protocols have not been followed.[59]

HCV is inefficiently transmitted by sexual intercourse (prevalence ranging from 1.3 percent in North America to 27 percent in Asia in long-term partners), although MSM, persons with multiple sexual partners, and HIV patients have higher rates of seroprevalence for HCV than do monogamous heterosexuals. The average risk for vertical transmission is 6 percent overall and 17 percent in mothers with HIV, which appears to be related to viral titer. No difference in transmission is noted whether the child is breast- or bottle-fed.

HCV is detected in serum, saliva, urine, semen, and ascitic fluid. There is no demonstrated fecal-oral or arthropod-borne transmission.

Pathogenesis

The pathogenesis is poorly understood, but HCV is not integrated into host genome like HBV. HCV has been difficult to culture but can be detected in serum hepatocytes within days of inoculation in experimental animals. The hypervariable region on genome allows for mutants (quasispecies) to emerge soon after infection is established. This quasispecies variability provides escape from effective host immune responses. Cell-mediated immune response causes the manifestations of HCV disease. Vigorous T-cell-mediated immune response is associated with resolution of acute HCV infection, whereas predominantly B-cell (antibody-mediated) response is associated with chronic HCV infection.[1'3'25'48'51'52'54]

CLINICAL FEATURES

The incubation period ranges between 15 and 160 days (2–26 weeks [mean, 36–49 days]). Shorter incubation (mean, 4 weeks) is seen after transmission through transfused blood products. The patient is usually asymptomatic; only 25 percent of patients with acute HCV develop jaundice. Fulminant hepatitis occurs in less than 1 percent. Fatigue, abdominal pain, and hepatomegaly are the most common clinical presentations. The course may resemble HBV but generally is more indolent.

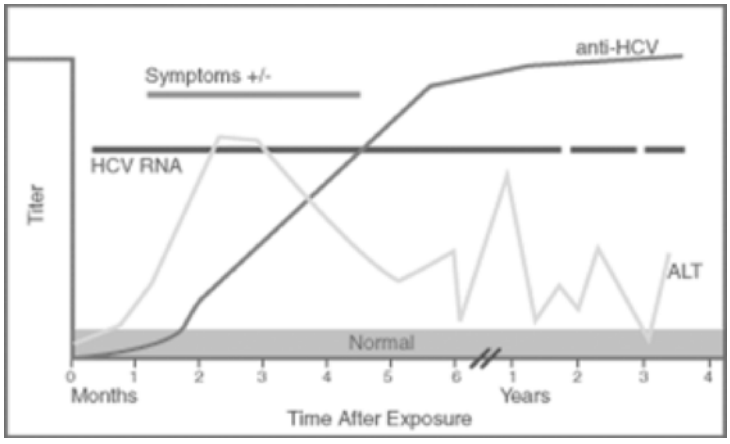

Figure 97-4.

Typical time course of clinical and serological events in Hepatitis C virus infections (From **http://www.cdc.gov/ncidod/diseases/hepatitis/slideset/index.htm**).

View Image

Chronic HCV infection occurs in up to 85 percent of cases (Figure 97-4). Of these, 20 percent develop cirrhosis (average 21 years following infection), 50 percent have asymptomatic persistent elevations of transaminases, and 30 percent remain HCV carriers without evidence of disease. First symptoms may

be liver failure or portal hypertension as a result of the cirrhosis. Also, 25 percent of patients with HCV-associated cirrhosis develop HCC (average 29 years following infection).

Consumption of alcohol aggravates liver damage from HCV and is a significant risk factor for progression from chronic HCV to end-stage liver disease. Other risk factors for complications of HCV infection include male gender, under 40 years of age at exposure, HIV co-infection, abnormal ALT, and fibrosis on biopsy. Nonhepatic complications occur, such as type II cryoglobulinemia, membranoproliferative glomerulonephritis, and porphyria cutanea tarda.[1,3,11,25,47,48,50,51,52,54,55,60]

LABORATORY DIAGNOSIS

Detection of antibodies to HCV (anti-HCV) by enzyme immunoassay (EIA) has evolved as more HCV protein fragments are incorporated into the test (see Figure 97-4). Current assays detect more than 90 percent of HCV infections as early as 6 to 8 weeks after exposure, though seroconversion may be delayed up to 20 weeks in 10 to 20 percent of patients. Sensitivity of testing is approximately 95 percent, but false-positive results may occur. In low-risk populations such as blood donors, 40 percent of all samples positive for HCV by EIA were found to be falsely positive.[61]In the past, a positive EIA test required a second-generation recombinant immunoblot assay as confirmation. However, this test is no longer available in the United States, so confirmation is by HCV polymerase chain reaction (HCV-PCR). The reverse-transcription PRC (RT-PCR) test can detect acute HCV infection as early as 1 to 2 weeks after exposure. The HCV-PCR is also used to monitor HCV viral load and its response to antiviral therapies. HCV RNA assays do not distinguish acute and chronic Hepatitis C.[1,3,25,50,51,54,62,63]Determining the level of viremia is important in gauging clinical response to treatment, so getting a quantitative RNA test is essential.[64]

Once the diagnosis of HCV is made, determining the genotype and extent of liver inflammation is important. Several genotype assays are commercially available, and knowing the genotype will guide treatment decisions (see below). Traditionally, the liver biopsy has been the standard tool to grade liver fibrosis. Based on the extent of fibrosis expansion, presence of bridging fibrosis, and presence/absence of cirrhosis, the extent of disease can be quantified through one of several scoring systems (histologic activity index, METAVIR, or Knodell).[65,66,67]Noninvasive techniques to estimate extent of liver fibrosis are also available. One such "multitest" uses an algorithm based on values of several laboratory markers to arrive at a screening tool that can detect severe liver fibrosis with a high negative and positive predictive value.[68]The assay is commercially available in the United States (FibroSURE, LabCorp, Burlington, NC). Another noninvasive method involves the use of transient elastography. This test is based on the concept that significant fibrosis can be detected by measuring liver stiffness through an ultrasound technique. It can discriminate between mild and more severe fibrosis[69]and was approved by the U.S. Food and Drug Administration (FDA) in 2013. The most recent version of the American Association of Study of Liver Disease (AASLD) guidelines from 2009 suggest the use of noninvasive testing to determine the presence of advanced fibrosis in chronic HCV but state that these tests should not replace liver biopsy in routine clinical practice.[70]

TREATMENT

For several years the treatment for HCV, regardless of genotype, was pegylated interferon plus ribavirin (PR). The standard way to assess treatment response is a sustained viral response (SVR), defined as undetectable viral load 24 weeks after the end of therapy.[71]PR has an adequate SVR for genotypes 2

and 3 (70 to 80 percent) but not as good for others, including genotype 1 (45 to 70 percent SVR).[70]

Additionally, PR is poorly tolerated, as the pegylated interferon causes flulike symptoms, fatigue, and headaches, and it is an injectable agent. For patients who did not respond to PR or were unable to tolerate it due to side effects, no real second-line options existed. Because of these concerns, substantial effort has been put forth in recent years by the scientific community to better understand the HCV viral genome and replication, with the goal of bringing to market agents that can better control viral replication with better tolerability.

The first target site for drug development is the NS3/NS4a protease. Blockage of this protease terminates the ability of the virus to spread to other cells. The first generation of HCV protease inhibitors were FDA approved in 2012 (boceprevir and telaprevir). Both of these agents were shown to be effective against genotype 1 when used in addition to PR, with SVRs of 63 to 75 percent.[72,73]

Additionally, in genotype 1 patients who did not respond to PR previously, many responded to the new three-drug regimen of PR plus a protease inhibitor (59 to 66 percent SVR versus 17 to 21 percent SVR with PR alone).[74,75]These results led the AASLD to revise its guidelines and recommend triple therapy for both treatment-naïve and treatment-experienced genotype 1 patients.[76]However, many drawbacks remain. In this regimen, the side effects of PR are still present, with additional side effects from boceprevir and telaprevir (severe rash). Both these agents also have multiple drug interactions and multiple daily dosage requirements, and they are ineffective against most non-genotype 1 viruses. Additionally, as these are direct antiviral agents (DAAs), they carry the risk of drug resistance.[71]

Over the next several years, additional DAAs will become available to overcome these existing drawbacks. For instance, the next protease inhibitor, simepravir, is dosed once daily and has fewer side effects. In a phase III study, the combination of simepravir + PR was shown to be effective against genotype 1, with SVR of 75 to 86 percent, even with a shorter treatment course. There are at least 10 additional protease inhibitors currently in various phases of development, including second-generation agents that have a high barrier to resistance and are potentially active against all four major HCV genotypes.[77]

In addition to protease inhibitors, several other classes of agents are in development. One such class is the NS5b polymerase inhibitors. The polymerase inhibitor in the most advanced stage of development is sofosbuvir. This agent has been shown in phase III studies to achieve SVRs of more than 90 percent when used in combination with PR against genotypes 1 and 4, as well as an SVR of 97 percent against genotype 2 when used with ribavirin alone (it only achieved an SVR of 56 percent against genotype 3, however).[78]A third class of new DAAs includes medications such as daclatesvir, which appear to be effective against multiple genotypes.[77]

There are in fact over 40 DAAs currently in development, signaling a new era for HCV treatment.[71,77]

The goal of having all oral regimens effective against all genotypes with good tolerability and easy dosing seems to be within reach. The development of drug resistance is a concern, but this will likely be overcome by using combinations of DAAs from different classes, a strategy similar to the highly active antiretroviral therapy (HAART) that has been so effective for HIV. One such all-oral regimen has been shown to be effective.[79]

PREVENTION

The risk of posttransfusion HCV has been dramatically reduced since the late 1980s with the institution of policies calling for the screening of blood donors for risk factors and testing them for anti-HCV. Similar rigorous testing is applied to donors of organs and tissues. Solvent-detergent or heat treatment of acellular blood products such as clotting factors and immune globulins inactivates many viruses, including HCV. Avoidance of exposure is the cornerstone of prevention of HCV infection. Uniform application of Standard Precautions in healthcare settings should effectively interrupt healthcare-associated transmission.

Individuals can avoid HCV infection by modifying behaviors that place them at risk. HCV carriers should be counseled to avoid transmitting the virus to others by not sharing razors or toothbrushes and by using condoms for sexual intercourse for those with multiple partners. HCV carriers should not attempt to donate blood, organs, tissues, or semen.[80]

Postexposure prophylaxis using immune globulin is ineffective in preventing HCV and is no longer recommended. Development of a vaccine to prevent HCV infection has been problematic because of viral antigenic diversity and mutation. Therefore, no HCV vaccine is yet available. Pregnancy is not contraindicated for HCV-infected women, as the risk of perinatal transmission to the child averages 5 to 6 percent. Breastfeeding has not been implicated in transmission of HCV and is encouraged.[81]

Needle exchange programs have proven effective in preventing the spread of HCV among injection drug users. Immunization against HAV and HBV is recommended in patients with HCV infections; Twinrix (combined HBV and HAV vaccine, manufactured by GlaxoSmithKline) may be used.[1,2,3,21,27,50,54]

Hepatitis D

TRENDS

Hepatitis D is also known as Hepatitis delta agent and was discovered in 1977.

EPIDEMIOLOGY

Description

HDV is an RNA virus with the smallest genome of all known animal viruses. This genome encodes a single antigen, which is expressed in two forms. HDV resembles plant satellite viruses but not other animal viruses. HDV has some genetic heterogeneity that varies geographically. It depends on simultaneous infection with HBV for its hepatotropism and transmission and is thus considered a parasite of HBV.[1,3,18,53,82,83,84,85,86]

Incidence

Approximately 5,000 to 7,500 new HDV infections occur per year in the United States, principally among IV drug users. The incidence of HDV among patients with hemophilia has declined since the 1980s as a result not only of screening blood and plasma donors for HBV infection but also of solvent-detergent or heat inactivation of viruses in clotting factors and the development of recombinant factors VIII and IX.[2,22,26,39]

Prevalence

Approximately 10 percent of HBV-infected individuals worldwide are co-infected with Hepatitis D. HDV is endemic in Italy and other countries in the Mediterranean basin, western Asia, northern South America, and certain Pacific islands. In western Europe and North America, the seroprevalence of HDV in blood donor populations ranges from 1.4 to 8 percent. The highest prevalence in the United States is among injection drug users (20 to 67 percent of HBV-infected persons). In Taiwan, 91 percent of HBsAg-positive injection drug users are also seropositive for HDV. Historically, 48 to 80 percent of U.S. patients with hemophilia were seropositive for HDV markers, but this rate is declining. Groups at intermediate risk of HDV infection include hemodialysis patients and institutionalized persons. HCP are at risk of acquiring HDV infection via sharps injuries.[1,12,18,82,84]

Transmission

HDV is transmitted principally by percutaneous exposure, but unlike HBV infection, HDV is inefficiently transmitted by sexual intercourse. Perinatal transmission is very rare, and no cases have been documented in the United States. It is not transmitted by the fecal-oral route or casual contact, though routes of transmission in countries in which HDV infection is endemic are not always clear.

Pathogenesis

HDV infection and hepatotropism depend on simultaneous infection with HBV, as the viral envelope for Hepatitis delta virus is the Hepatitis B surface antigen. HDV replicates only in hepatocytes and may be cytopathic. HDV and HBV may co-infect a susceptible host; a person who is already a chronic HBsAg carrier can be superinfected with HDV.[1,3]

CLINICAL FEATURES

The incubation period of HDV ranges from 30 to 180 days. Simultaneous co-infection with HBV and HDV usually manifests much like acute HBV alone, though there may be a biphasic elevation of ALT with HDV infection. In 90 to 95 percent of cases of acute co-infection, the hepatitis is self-limited, and HBV and HDV are eliminated.

However, fulminant hepatic failure occurs more frequently than is seen with HBV alone. Approximately 5 percent of co-infections result in chronic HBV and HDV infection, a rate that is similar to that of HBV infection alone. Superinfection with HDV in a patient who is a chronic HBsAg carrier often causes more severe acute hepatitis than is seen with HBV/HDV co-infection. Moreover, HDV superinfection results in chronic HDV in greater than 90 percent of survivors of the acute infection. In 10 to 15 percent of these, especially among IV drug users, hepatic damage may progress to cirrhosis and liver failure within 1 to 2 years. Most of the others with chronic HDV have more slowly progressive liver disease resembling chronic HBV. HCC is less common in patients with chronic HDV infection than it is with chronic HBV or HCV. The reasons for this are not clear.[1,3]

LABORATORY DIAGNOSIS

A diagnosis of HDV is not tenable unless the patient tests positive for HBsAg. HDV should be suspected when there is a history of percutaneous or sexual exposure in a patient with chronic HDV infection, especially an IV drug user. It should also be suspected in a patient with acute HBV who has a second rise in ALT level or a patient with chronic HBV who develops an acute exacerbation of hepatitis.

The diagnosis of HDV can be made by PCR, IgG anti-HDV, or IgM anti-HDV. The first test should be anti-HDV IgG.[87]Co-infection of HBV and HDV is suggested by the simultaneous finding of a positive test for IgM anti-HBc. The anti-HDV IgG is short-lived in co-infection and is not protective. It may remain

elevated as a "serologic scar" in superinfection patients who clear their HDV infection. A positive anti-HDV IgG should be followed up with HDV PCR to evaluate for evidence of active infection.[87]

TREATMENT

In acute HDV, supportive care is given. For chronic HDV, high-dose interferon alfa (IFN-a) may induce remission of disease in 40 to 50 percent of selected patients with histologic and biochemical response as well as viral suppression. However, relapse viremia is common and effects are unlikely to last once therapy is stopped.[88]The side effects of interferon therapy may be a severe limitation to its use.

Regarding antiviral medications, lamivudine has been shown to be ineffective,[89]but tenofovir has been shown in a small study to decrease HDV viral loads, particularly when used with interferon.[90]In acute fulminant HDV or end-stage hepatic failure or cirrhosis, liver transplantation is often necessary.[7,18,19,53,82,84,85,86]

PREVENTION

General preventive measures for HDV, as for HBV, include modification of high-risk behaviors by individuals. Standard Precautions are used in healthcare settings. Postexposure passive immunization with HBIG with HBV vaccine can prevent infection with HBV. By eliminating HBV, co-infection with HDV will not occur. Preexposure active immunization with HBV vaccine will prevent co-infection with HDV. No vaccine to prevent HDV superinfection is yet available. Patients with chronic HDV infection should be candidates for HAV vaccine. Needle exchange programs may be effective in preventing the spread of HDV among injection drug users.[1,2,3]

Hepatitis E

TRENDS

Hepatitis E is unique among the hepatic viruses in that it carries a particularly high mortality rate among pregnant women.

EPIDEMIOLOGY

Description

HEV is a small RNA virus in the Hepeviridae family. Its genome was cloned and sequenced in 1990 and 1991. The HEV genome encodes the synthesis of several proteins, and there is substantial worldwide geographic divergence among genotypes. However, only one common serotype has been found, which has been useful in developing serological tests for HEV. HEV is detected in serum during prodromal infection and in feces as infection progresses.[1’3’17’86’91’92]

Incidence

HEV is thought to cause at least 50 percent of sporadic acute viral hepatitis in developing countries, where it is also the most common cause of epidemics of enterically transmitted viral hepatitis. Epidemics of HEV seem to occur cyclically related to heavy rainfall and flooding in endemic areas. The peak incidence age is 15 to 40 years old. Attack rate is 1 to 10 percent, and secondary cases occur in 3 percent of contacts. HEV is endemic in the former Soviet Union and equatorial developing areas,

especially south Asia, Africa, Mexico, and Central America. In these areas, HEV occurs sporadically as well as in periodic epidemics. Large epidemics occurred in India in 1955 to 1956 (30,000 cases) and China in 1986 to 1988 (120,000 cases). In Thailand, 3.6 percent of adolescents and 15.7 percent of adult blood donors have serological evidence of previous HEV. The reservoir for HEV in endemic areas may be zoonotic infection in swine, chickens, and rats. Contamination of water sources by feces from these animals may result in sporadic cases, as well as epidemics during floods and widespread disruption of sanitation. In the United States, clinically recognized HEV is generally seen as isolated sporadic cases in persons who have recently traveled to an endemic area. No secondary cases in household contacts have occurred in the United States.[1'3'12'16'17'26'85'91'92]

Transmission

Transmission is fecal-oral generally via ingestion of contaminated water, and there is a strong association of epidemics with floods, poor sanitation, and poor hygiene. Rare transfusion-associated cases have occurred; sexual transmission has not been documented. Infection during pregnancy results in a high frequency of fetal loss, and vertical transmission can occur in up to 50 percent of cases.[93]

Pathogenesis

Animal studies show replication of HEV in liver, blood cells, and other organs. Early liver damage may result from direct cytopathic effect of HEV, but later pathologic effects are immune mediated. HEV is transiently present in serum during prodrome, and at the onset of clinical disease it is found in feces. Fecal shedding of HEV persists for 1 week to 2 months. Appearance of anti-HEV roughly correlates with cessation of viral replication and beginning resolution of disease.[1'3'17]

CLINICAL FEATURES

The incubation period of HEV is between 2 and 9 weeks (mean, 45 days), and it is generally a self-limiting disease that is relatively severe compared with HAV. There is a prodromal (pre-icteric) phase of nonspecific constitutional symptoms followed by an icteric phase that lasts several weeks. Fulminant HEV is rare (0.5 to 4 percent) except in pregnant women, in whom HEV occurring in the third trimester carriers a 20 percent maternal fatality rate and a 50 percent rate of fetal loss. Mortality rate of those infected during the third trimester was 100 percent in one study.[93]There is no chronic hepatitis or carrier state in humans with HEV.[26'60'85]

DIAGNOSIS

Usually, clinical syndrome plus travel history are the first clues to suggest HEV. Exclusion of other causes of hepatitis heightens suspicion for HEV. Previously, the only available HEV-specific serologic tests used recombinant antigens and had a high rate of false positives in low-prevalence settings such as the United States (false-positive rate of 3 percent of U.S. blood donors). However, two recently developed tests (includes the HEV IgM ELISA 3.0 and the Rapid Point of Care test) have been shown to be highly sensitive and specific.[94'95]These are now diagnostic tests of choice, and the Rapid Point of Care test is particularly useful in endemic regions, as it is highly specific (98.6 to 99.7 percent specificity)[94'95]and does not require advanced laboratory equipment.

TREATMENT

Supportive care should be provided, as for any acute hepatitis. With fulminant HEV, liver transplantation is indicated.[1,3]

PREVENTION

In endemic areas, prevention is primarily achieved on an environmental level by ensuring separation of the water supply from sewage. During outbreaks when sanitation has eroded, efforts such as water chlorination may be inadequate.[96] Boiling or other disinfection of the water supply should still be attempted, and avoidance of uncooked fruits, vegetables, and shellfish in these settings is also prudent. Pregnant women should be cautious about travel to endemic regions due to elevated mortality risk. Unlike with HAV, passive immunization with IG has not been shown to protect against HEV transmission or disease. Several potentially effective prototype HEV vaccines are being studied but none is yet available.[97] Standard Precautions are adequate to prevent HEV transmission in healthcare settings. The finding of asymptomatic carriage of HEV in swine raises concern of xenotransplantation from pigs to humans.[1,2,3,15,17,26,98]

Conclusions

In summary, HAV is an enteric transmitted virus that has an acute viral syndrome with no chronic disease state that is diagnosed by HAV IgM serological marker and has an effective vaccine and passive immunoprophylaxis with IG, which is very effective if given before or within 2 weeks after exposure. HBV is a bloodborne virus with both an acute viral syndrome and a chronic disease state and is diagnosed by anti-HBcIgM and/or HBsAg serological markers. It has an effective vaccine and passive immunoprophylaxis with IG that is very effective if given within 7 days of exposure. HCV is a bloodborne virus whose transmission is very high among injection drug users, is characterized by a chronic disease state, is diagnosed by anti-HCV and HCV-PCR, and has no effective vaccine. HDV is a bloodborne virus that is principally transmitted like HBV by percutaneous exposure, but not efficiently by sexual intercourse, and is characterized by both an acute syndrome and a chronic disease state (that persists in patients with chronic HBV). HEV is an enteric transmitted virus that has an acute viral syndrome with no chronic disease state that is diagnosed by HEV IgM serological marker or PCR. It has no effective vaccines, and the best prophylaxis is improvement of sanitary conditions.

Future Trends

With regard to HAV and HEV, the proportion of adult patients affected by foodborne HAV may continue to expand following the elimination of person-to-person epidemics among children. In recent reports, 11 percent of the population over 60 years of age in specific developed countries were susceptible to HAV infection. With regard to HBV, there is a decrease in transmission among HCP because of Standard Precautions, OSHA-mandated immunization, and the use of HBV HBIG. Liver transplantation will continue to be a viable treatment for liver failure secondary to HBV. With regard to HCV, the epidemic is peaking. A new era in treatment of HCV has arrived with the availability of directly acting antiviral therapy. Interferon-free therapy, especially for genotype 2 or 3 infection, will likely soon be standard practice.

International Perspective

Complications of cirrhosis and HCC from chronic HBV and HCV remain the leading causes of liver-related death worldwide. The incidence of HBV and HCV in the populous areas of Asia and Africa remains the critical underlying problem. Perinatal prophylaxis in patients with active HBV remains critical in controlling the worldwide epidemic. HAV continues to be prevalent in nonindustrialized countries among children. HDV and HEV have very high prevalences in specific areas of the world. Control of the bloodborne viruses will depend on precautionary measures with blood supply and intravenous drugs, whereas control of the enteric viruses will depend on the increasing sanitation systems and food-handling practices.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

West Nile Virus

Author(s): Michael A. Pentella, PhD, CIC, D (ABMM)

Published: October 3, 2014

Abstract

*Since introduction into the Western Hemisphere, West Nile virus (*Flaviviridae: Flavivirus*) has established enzootic transmission in nearly every part of the United States and southern Canada and has become an important public health concern. Although approximately 80 percent of individuals infected with West Nile virus are asymptomatic, others have clinical manifestations ranging from febrile illness to neurologic syndromes and possibly death. West Nile virus has a broad host and vector range with competent mosquito and bird vectors, which has led to the establishment of the virus throughout the Western Hemisphere. Although it is primarily transmitted through the bite of an infected mosquito, other modes of West Nile virus transmission have been identified and include infection through transplants of infected organs, transfusion of blood or blood products, intrauterine fetal infection, neonatal infection through breast-feeding, occupational exposure in the field, and laboratory-acquired infections from needlestick or sharps injuries. Controlling the spread of West Nile virus, as well as other emerging vectorborne viral disease, requires laboratory diagnostic testing in conjunction with epidemiologic surveillance, vector control programs, and a variety of personal precautions. No human vaccine is currently available; however, there is an equine vaccine.*

Key Concepts

- West Nile virus is an arthropodborne virus (arbovirus) primarily transmitted through the bite of infected mosquitoes.
- Approximately 80 percent of people infected with West Nile virus are asymptomatic; those with symptoms usually experience a mild febrile illness.
- A very few (less than 1 percent) go on to develop neurologic manifestations of encephalitis or flaccid paralysis.

- West Nile virus is a seasonal disease; a variety of personal precautions to protect against mosquitoes and reduce mosquito populations can be performed to prevent infections from West Nile virus and other arboviruses effectively.

Background

West Nile virus (WNV) was first identified as a pathogen from a woman with a febrile illness in the West Nile District of Uganda in the 1937.[1]Prior to its appearance in the United States, it was considered to be of low virulence. Before WNV appeared in New York in 1999, it had never been seen in the Western Hemisphere. The resulting epizootic (large disease outbreak in animals) developed into an ongoing epidemic of a mosquito-transmitted viral disease in the United States and the largest recorded outbreak of WNV in the world. At the peak of the WNV outbreak in 2003, there were 9,862 cases reported, with 2,866 cases of neuroinvasive disease and 264 fatalities in the United States. Since then the incidence has waned, and in 2008 there were 1,370 cases reported with 640 neuroinvasive disease and 37 fatalities in the United States.[2]In 2012, an increase in infections was detected with the highest number of cases reported since 2004.

It is thought that the strain of WNV that is being transmitted in the Western Hemisphere is more virulent than strains seen prior to 1999 outside of the United States.[3]WNV is now established in North America and can be considered a seasonal disease that strikes every summer and into the fall.

Definitions And Basic Principles

DEFINITIONS

*Arthropods:*insects that include mosquitoes, ticks, and biting midges

*Arbovirus:*a contraction of the words *ar*thropod-*bo*rne *virus*; these are viruses that are transmitted by arthropods; arthropods serve as a vector for transmission

*Amplifying host:*vertebrate host that serves as a reservoir for an arbovirus; infection with the arbovirus results in high titers of virus in the circulation

*West Nile fever:*uncomplicated febrile illness resulting from WNV infection

*West Nile neuroinvasive disease (meningoencephalitis):*clinical syndrome used to describe encephalitis, meningitis, myelitis, or overlapping syndromes of each resulting from WNV infection

BASIC PRINCIPLES

WNV is a flavivirus and member of the Japanese encephalitis virus complex; this includes WNV, Japanese encephalitis, St. Louis encephalitis, and Murray Valley encephalitis viruses. They also are closely related to other well-known flaviviruses, dengue and yellow fever viruses. The relative amount of an arbovirus present in the environment is the result of a complex interaction between the virus, its arthropod vector, and the specific amplifying host. Each arbovirus has specific amplifying hosts (e.g., birds, small vertebrate mammals, or rodents) that serve as the primary reservoir in the environment. For WNV, birds are the primary amplifying host because when they become infected they develop high levels of viremia that allow for ease of transmission. Mosquitoes, the arthropod vector for WNV, become

infected during the blood meal and serve to transmit the virus and maintain the bird-mosquito-bird cycle. *Culex*spp. mosquitoes are the primary vectors transmitting WNV. *Culex*spp. permit the virus to winter over in temperate climates, because they hibernate as infected adult mosquitoes. In the spring, the mosquitoes emerge and infect birds. This is a self-perpetuating cycle because there are ample numbers of mosquitoes to serve as vectors and birds to serve as susceptible hosts. Humans and horses are not integral to this amplification cycle and are considered incidental, or dead-end, hosts. When humans and large mammals are infected, the level of viremia is low enough and presents for a short enough duration that the mosquito vector taking a blood meal is unlikely to acquire the infecting arbovirus.

Virology, Epidemiology, And Clinical Management

CHARACTERISTICS OF WEST NILE VIRUS

WNV is a small, enveloped virus with a single-stranded RNA genome of approximately 11,000 nucleotides. There are two phylogenetic lineages of WNV that are separated based on genome homology: Lineage 1 is distributed worldwide (West Africa, the Middle East, Eastern Europe, North America, and Australia), whereas lineage 2 is limited to Africa. The virus introduced into New York in 1999 is most closely related to a lineage 1 virus isolated from a goose in Israel in 1998, though the exact mechanism of the introduction is unknown.[4]

EPIDEMIOLOGY SURVEILLANCE ACTIVITIES

West Nile Virus Transmission

WNV is primarily transmitted by the bite of infected mosquitoes. Birds serve as the primary reservoir host and mosquitoes are the arthropod vector. For example, *C. pipiens*(the northern house mosquito) is a major arthropod vector within the WNV transmission cycle. *C. pipiens*prefers to feed on birds and lays its eggs in standing, "dirty" water commonly found in urban areas (i.e., catch basins, pool covers, birdbaths, discarded tires). WNV has been shown to infect hundreds of bird species; most survive the infection. The resulting infection causes a high-titer viremia for many species, which aids in acquisition of the virus by mosquitoes taking a blood meal. WNV spread rapidly across the United States and Canada from 2001 through 2004 by means of migratory birds that fly south to Central and South America in the fall and back north in the spring to the United State and Canada along specific flyways. Major outbreaks were observed 1 year after introduction via migratory birds, probably through distribution in resident birds.[5]Humans are incidental hosts for WNV, as are other mammals, including horses.

Novel Modes of West Nile Virus Transmission

Healthcare-associated transmission of WNV through contaminated blood, blood products and organs, and from mother to child through breast milk has been identified. In the fall of 2002, healthcare-associated infection with WNV occurred in four recipients of organ donations shortly after transplantation. Because each patient had received organs from a single donor, the transplanted organs were identified as the route of acquisition.[6,7]Further investigation of this case determined that the organ donor became infected after transfusion with WNV-contaminated blood products. Additional investigations determined that donation of blood and blood products by WNV-infected individuals before the development of symptoms has the potential to transmit the virus to the recipients of the products.[8]As a

result, in July 2003, the U.S. Food and Drug Administration (FDA) mandated WNV screening of blood products.

Workers at risk for occupational exposure include (1) those who work outdoors such as farmers, foresters, landscapers, etc. and (2) laboratory,[9]field, and clinical workers who have contact with infected animals and blood, perform necropsies of infected birds, or handle WNV-infected tissues or fluids.[10]

Heathcare personnel should be educated regarding the risk of transmission of WNV through blood and body fluids and educated that Standard Precautions are appropriate.[11]WNV also has been shown to be transmitted from mother to child vertically[12]and through breast-feeding.[13]

Clinical Manifestations of West Nile Virus Infection

Being bitten by an infected mosquito does not necessarily cause symptomatic illness. After a mosquito bite, the incubation period may be as short as 2 days or as long as 14 days. The virus enters the lymph nodes and multiplies before entering the bloodstream. An infected person is infectious for 6 to 7 days before the onset of clinical illness, but infectiousness ends shortly after symptoms appear. Approximately 80 percent of people who are infected with WNV are asymptomatic, but approximately 20 percent of infected individuals experience a mild febrile illness, which can be severe but is usually self-limiting; besides a fever, symptoms include fatigue, headache, muscle weakness, neck pain or stiffness, eye pain, malaise, anorexia, nausea, vomiting, and rash. This febrile illness is known as West Nile fever. In less than 1 percent of individuals, WNV can cause encephalitis, meningitis, or a polio-like flaccid paralysis[3]that can lead to permanent neurological sequelae and death. The risk for serious disease increases with age and in immunocompromised patients. Symptoms of West Nile encephalitis include the rapid onset of severe headache, high fever, stiff neck, confusion, loss of consciousness, and muscle weakness. Symptoms of mild WNV disease usually last for only 3 to 6 days; however, WNV fever can be a serious illness requiring several months or longer to resolve.[14]

Laboratory Diagnostic Testing

Testing should only be performed on patients who have symptoms suggestive of WNV, such as headache, fever, stiff neck, and muscular weakness, and a diagnosis of encephalitis and/or meningitis. The preliminary diagnosis of WNV infection can be based on the patient's signs and symptoms, risk of exposure such as activities that would expose them to mosquito bites, travel history, or the incidence of WNV from surveillance data of the location where the infection is thought to have occurred.

WNV infection can be detected with acute or convalescent phase serum by serological assays, which utilize enzyme immunoassay (EIA) immunoglobulin M (IgM) antibody capture method. Cerebrospinal fluid (CSF) can also be tested for IgM antibodies by EIA. There are several FDA-approved tests available in the United States.[15]It is important to note that the degree of proficiency may vary between laboratories.[16]The positive results obtained with a commercially available product need to be confirmed by testing at a state public health laboratory or the U.S. Centers for Disease Control and Prevention (CDC). Although antibody may be absent when symptoms first develop, greater than 90 percent of WNV-infected individuals have detectable antibodies by day 8 postinfection. If the IgM WNV antibody is positive in blood or CSF and confirmed by another method, it is likely that the person has a current WNV infection or that they had one in the recent past. If the IgM antibody is detected in the CSF, it suggests that the WNV infection is present in the central nervous system. If IgM WNV and immunoglobulin G (IgG) WNV antibodies are detected in the initial sample, it is likely that the person contracted the WNV infection at

least 3 weeks prior to the test. If the IgG WNV antibody is positive and the IgM WNV antibody level is low or not detectable, it is most likely that the person was previously exposed to WNV but is not currently infected. If WNV IgG antibody titers in convalescent samples continue to rise, this change would indicate a more recent infection. If the WNV IgG antibody levels have not changed or have decreased, this would indicate a past but not recent infection.

The presence of WNV antibodies may indicate an infection, but they cannot be used to predict the severity of an individual's symptoms or their prognosis. Testing of single serum specimens from "worried well" or mildly symptomatic patients is typically not indicated because the clinical impact of a positive result in these cases is minimal.

A nucleic acid amplification test (NAAT) for WNV is available. This test amplifies and measures WNV genetic material to detect the presence of the virus. This test can detect a current infection with the virus often before antibodies to the virus are detectable. Although it can specifically identify the presence of WNV, there must be a sufficient amount of viral particles present in the sample to detect it. Because humans are secondary hosts of WNV, virus levels in humans are usually relatively low and do not persist for very long. A NAAT may detect WNV as long as the virus is actively replicating in the person. Therefore, when a patient becomes symptomatic, NAAT for WNV is not useful. Nucleic acid testing is most useful as a screen for WNV in donated units of blood, tissue, or organs; for detecting WNV; and for testing birds and mosquito pools to detect the presence and spread of WNV in the community. It is possible to determine that WNV has spread to a particular area and is in the mosquito population before any human cases are identified. NAAT also may be used to test the blood or tissues postmortem to determine whether WNV may have caused or contributed to death. A negative test cannot be used to definitively rule out the presence of WNV.

Culture for WNV is rarely performed and requires use of Biosafety Level 3 (BSL-3) laboratory precautions, which necessitates special engineering controls for the laboratory and additional procedural precautions and protective equipment for the staff (see *Biosafety in Microbiologic and Clinical Laboratories*in Supplemental Resources at the end of this chapter for additional information on laboratory biosafety). As such, performance of plaque reduction neutralization test (PRNT) and other arboviral culture methods are mostly available only at some state public health laboratories and the CDC.

NAAT and viral cultures are used in research settings to identify the strain of virus causing the infection and to study its attributes. Different strains of WNV have been isolated and associated with different epidemics around the world.

Because the likelihood of virus being present in any clinical specimen from suspect cases is low, Standard Precautions for specimen collection and handling are appropriate.

Testing of Blood, Blood Products, and Organs Prior to Transfusion or Transplantation

In May 2003 prior to the mosquito season, the FDA implemented "Guidance to Industry" recommendations for assessing donor suitability and product safety for donors with proven WNV infections or with illnesses potentially caused by WNV.[17]The guidance originally recommended deferral of donors who reported fever with headache in the week before donation. It also recommended that blood-bank facilities encourage donors to self-report post donation illnesses that could be WNV. Subsequently, data indicated that self-reporting of fever with headache did not predict WNV-contaminated product, and it was eliminated. In December 2005, the FDA approved the first test to screen for WNV in donors of blood organs, cells, and tissues. Thus a screening test, NAAT, is used for blood donor screening in the

United States. Donors are deferred for 120 days after WNV disease or a positive test.[18]The policy has been successful at preventing healthcare-associated transmission of WNV through the screening of donor's blood, blood products, and organs for transplantation.

Treatment of West Nile Virus Infections

Treatment for severe WNV illness is supportive care; this can involve hospitalization, intravenous fluids and nutrition, respiratory support, and prevention of secondary infections. There is no specific antiviral therapy. There are three equine WNV vaccines licensed for use in the United States, and the human vaccine is in clinical trials.

Practices to Reduce the Risk of West Nile Virus Infection

Education of the public regarding protection and avoidance is an important mechanism for WNV prevention. The public should be informed of the modes of transmission and the importance of preventing mosquito bites throughout the entire mosquito season. This activity provides protection not only against WNV infection, but also against other diseases transmitted by mosquitoes. Individuals should be advised to take personal protective measures to reduce the risk of exposure to mosquitoes, particularly around dusk and dawn, when mosquito feeding is most active. Applying insect repellent to skin, wearing protective clothing, and minimizing outdoor activities during peak mosquito-feeding times are effect prevention strategies.[2]Because mosquitoes lay their eggs in standing water, risk reduction activities should also focus on eliminating these potential breeding sites and preventing access of adult mosquitoes to dwellings by ensuring that window and door screens are intact and fit tightly. Examples of risk reduction activities and descriptions of biological and chemical agents for mosquito control are detailed elsewhere.[2]

Conclusions

Since WNV first appeared in the United States in 1999, it has caused a significant number of cases of acute morbidity and mortality. The future dimensions of the WNV epidemic remain unknown. WNV is transmitted to humans primarily through a bite of an infected mosquito. The vast majority of those infected are asymptomatic. Of those who do have signs and symptoms, the vast majority have a mild febrile illness; a fraction of those will have neurologic syndromes and possibly death. The risk of severe illness increases with age and in immunocompromised hosts. There is no antiviral therapy or vaccine. This continuing epidemic of WNV serves as an example of the threat an emerging agent poses to a vulnerable population.

Future Trends And Research

CLINICAL

A great deal has been learned of the short-term morbidity and mortality of WNV infection, but there remains much to be studied about the long-term clinical, neurological, and functional sequelae that result from West Nile neuroinvasive disease. The long-term aspects of WNV pose a significant source of morbidity to patients well past the acute illness.

ECOLOGICAL

The ongoing WNV epidemic serves as a model for other potential emerging vectorborne viral diseases such as Rift Valley fever and has refocused our attention on arboviral diseases. Reinvestment of resources has allowed for studies in a variety of areas of the WNV environmental cycle that may have implications for related arboviruses, such as St. Louis encephalitis. Results from these studies not only will answer basic questions about WNV but also should assist in managing future outbreaks.

International Perspective

WNV is one of the most widely distributed flaviviruses worldwide. Besides North America, WNV has a geographic range that includes Africa, Europe, the Middle East, west and central Asia, and Oceania during the past decade. It is expected to continue to spread into Central America and eventually South America as well. However, to date, the incidence of illness in the Caribbean, Central America, and Mexico is low—this is in spite of serologic evidence of substantial WNV activity. The reason for the decrease in morbidity needs to be further studied but may be due to a number of reasons such as the presence of other flaviviruses in the area.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Parasites

Author(s): Jan Lienau, BSN, RN, CIC
Infection Preventionist II

Greer Medical Campus
Greenville Health System
Greer, SC

Published: October 3, 2014

Abstract

A parasite is defined as any organism living within or on another living creature and deriving advantage from doing so while causing disadvantage to the host. Parasites may spend part or all of their life cycle with the host. The epidemiology and transmission of most parasites is well defined. Parasites are rarely spread by direct person-to-person contact; therefore, they usually require little attention from infection preventionists. However, infestations with ectoparasites or epidermal parasites are fairly common among the community and healthcare facilities and can be responsible for infections of the epidermis or external layer of the skin. Healthcare-associated transmission has been reported with scabies, lice, and maggots. This chapter focuses on parasites (primarily ectoparasites) that may directly affect the healthcare setting but also briefly covers those that may be seen in individual patients.

Key Concepts

- Scabies and lice are transmitted through direct contact with infested persons.
- Outbreaks of scabies have been well described in hospitals, long-term care facilities, and other healthcare institutions.
- Humans are the only natural reservoir of scabies and body, head, and pubic lice.
- Treatment exists for both scabies and lice, although cases of resistance have been reported.
- Protozoa are single-celled amoebae, flagellates, ciliates, and tissue-dwelling organisms; however, most are not human parasites.
- Helminthes, including a variety of nematodes, cestodes, and trematodes, can cause human disease.

Basic Principles

SCABIES

Skin infestations by the mite *Sarcoptes scabiei*var. *hominis*(Figure 99-1) are commonly known as scabies. The adult mite has a round body and four pairs of legs; the female is larger than the male and measures less than 0.5 mm long.

The adult female is attracted to human skin predominantly by human odor and burrows in the upper layer of the epidermis, where she lays two to three eggs each day. The eggs require 10 days to progress through larval and nymph stages to form adult mites, which have a life span of approximately 1 to 2 months.[1,2,3,4]

EPIDEMIOLOGY

Humans are the natural reservoir of *S. scabiei*var. *hominis*. This parasite is not a vector of infectious agents. Mites are transmitted through direct contact with infested persons; less frequently, transmission may occur through contact with clothing or bedding (fomites). Spread of the mite to a different part of the body can occur by manual transfer or scratching. A slightly different mite causes scabies in dogs (*S. scabiei*var. *canis*) and may be transmitted to humans through direct contact with an infested animal. Infestation with *S. scabiei*var. *canis*is self-limited in humans.[1,2,3,4]

The female mite is capable of moving at speeds up to 2.5 cm per minute and can penetrate skin rapidly in 2.5 to 45 minutes. Mites can survive as long as 3 days on stuffed chairs, sofas, and tile floors, whereas nymphs can survive 2 to 5 days at 25°C and 45 to 75 percent humidity.

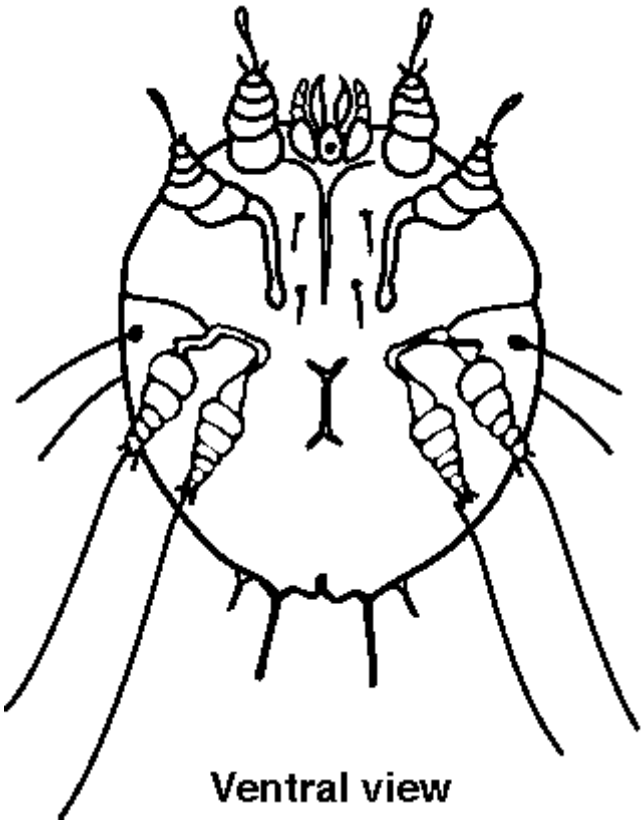

Figure 99-1.

Scabies (*Sarcoptes scabiei*).

View Image

Approximately 300 million annual cases of scabies occur worldwide. Persons infested with scabies are usually children, sexually active young adults, or persons who exist in close physical contact with large numbers of people. Outbreaks of scabies have been well described in hospitals, including nurseries and intensive care units, principally because of delayed recognition and lack of patient isolation. Reports indicate that scabies occurs in approximately 5 to 25 percent of long-term facilities annually and can also be spread in homeless shelters.[5,6,7,8,9]Outbreaks probably occur owing to large numbers of mites that reside under a person's fingernails while scratching. In a recent review, the mean number of infested patients per hospital outbreak was 18 (attack rate of 13 percent), and the mean number of infested healthcare personnel (HCP) was 39 (35 percent attack rate). Although control involves extensive treatment of patients, employees, and visitors, education to prevent mass hysteria and "psychogenic scabies" is often required.

CLINICAL PRESENTATION

The incubation period (exposure to onset of symptoms) for primary infestation occurs as early as 10 days but is typically 4 to 6 weeks. Because of previous sensitization, symptoms in patients with reinfestation usually appear in 1 to 3 days. Approximately two-thirds of cases have burrow-type pruritic lesions on hands, webs of fingers, wrists, and extensor surfaces of elbows and knees, as well as outer surfaces of feet, armpits, buttocks, and waist. Spread can also occur to arms, trunk, legs, penis, scrotum, and nipples. In geriatric patients, scabies often appears as excoriations and tends to present on the back. Variation in lesion appearance often leads to misdiagnosis. Dermatological manifestations include burrows, papules, scales, vesicles, bullae, crusts, pustules, nodules, and excoriations. The burrows often appear as grayish, threadlike elevations in the outer layer of the skin. Burrows occur less frequently in infants and children. However, there may be eczematous involvement of the head, neck, palms, and soles. This type of dermatological involvement is also seen frequently in immigrants and homeless individuals because of poor nutrition and sanitary conditions. In bedridden patients, scabies may be limited to sites in constant contact with sheets or nursing care, including the warm, moist skin environments of the buttocks and back.

The typical presenting symptom in most patients with scabies is intense pruritus, which is usually more severe at night. Scratching often produces bleeding and scab formation, thus leading to secondary bacterial infection, typically caused by group A streptococci and/or *Staphylococcus aureus.*

Nodular scabies is caused by hypersensitivity to mites; however, mites are seldom found in nodules present for more than 30 days. Characteristic lesions appear as reddish brown pruritic nodules on the male genitalia, groin, and axillae. Although nodular scabies often clears spontaneously, skin lesions may persist for more than 1 year despite treatment. Nodular scabies is found in about 7 to 10 percent of patients with scabies, particularly small children.

Crusted (Norwegian) scabies presents as a crusty, scaly dermatitis usually of the hands and feet, including dystrophic nails. Some affected individuals may have a generalized erythematous eruption. Norwegian scabies is highly contagious owing to the large numbers of mites present (ranging from thousands to millions compared with 3 to 50 for common scabies). Despite the large number of mites, itching is remarkably minimal. There appears to be a predilection for mentally challenged, chronically debilitated, homeless, or immunologically deficient persons (e.g., long-term corticosteroid use, immunosuppressive therapy, hematological malignancies, or acquired immunodeficiency syndrome [AIDS]).

SPECIAL CONSIDERATIONS IN PERSONS WITH HUMAN IMMUNODEFICIENCY VIRUS

There is a special predisposition of human immunodeficiency virus (HIV) patients to acquire "ordinary" scabies[10,11,12]that converts to crusted scabies as their CD4 cell counts fall. HIV-associated scabies can rapidly spread to other patients and HCP.[6,7]In some cases, crusted scabies may be the signifying condition in patients with previously undiagnosed HIV infection. About 20 percent of HIV patients with scabies have been reported to develop secondary bacteremia with *Staphylococcus epidermidis*, *S. aureus*, and Gram-negative rods.[12]Although a theoretical possibility, there has been no evidence that the scabies mite transmits HIV.

DIAGNOSTIC TESTS

Definitive diagnosis of scabies infestation is by microscopic examination of mites extracted by a needle or a scalpel. Using a hand lens, recent burrows should be identified and used to obtain skin scrapings. The skin scrapings are mounted on a slide with mineral oil and microscopically examined for eggs, mature and immature mites, and fecal pellets. Burrows can be more readily visualized by swabbing the suspected infestation area with India ink. After several minutes the excess ink should be wiped away, leaving the burrows darkly stained. Skin scrapings may be nondiagnostic in up to one-third of cases; therefore, repeated sampling is often necessary to confirm the diagnosis. Skin biopsies can also be performed, especially for atypical lesions or cases that cannot be diagnosed by skin scraping. Infection can also be detected by amplification of *Sarcoptes*DNA using polymerase chain reaction assay. Some patients with scabies may experience elevated immunoglobulin E titers.

TREATMENT

Treatment for scabies is usually a topical scabicide applied to the neck, trunk, and all extremities, including beneath fingernails. In infants, treatment may also require application to the scalp. Elderly patients frequently require facial and scalp application to eliminate the infestation. The drug of choice is one to two applications of 5 percent permethrin cream, which is left on the skin for 8 to 14 hours before thoroughly washing off. Treatment may be repeated in 5 days, especially in severe cases. Permethrin kills mites, lice, and other arthropods by disrupting sodium transport in their nerve cell membranes. This compound is poorly absorbed in mammals but may cause skin irritation.[1,2,3,4,8,9,11,12,13]

An alternative topical scabicide is 1 percent gamma benzene hexachloride (lindane) lotion. Unfortunately, excessive application of lindane and skin absorption has been associated with neurotoxicity and seizures, especially in young children. Sporadic drug resistance has also been reported. Other alternative topical treatments include 10 percent crotamiton (which requires several applications and is associated with a high treatment failure rate) as well as sulfur creams, malathion, and benzyl benzoate.[14]

The antihelmintic drug ivermectin, given as a single oral dose of 200 µg/kg (with an additional dose repeated 2 weeks later), can be considered to be an effective first-line systemic therapeutic option for scabies in otherwise healthy patients and many patients with HIV.[15,16,17]Unfortunately, ivermectin resistance has developed both in vitro and in vivo.[18]Furthermore, this drug can cause rare serious side effects.[19]

The hyperkeratotic lesions of crusted scabies may necessitate use of 6 percent salicylic acid or manual débridement before a scabicide can be applied. Systemic therapy with oral ivermectin may be advisable. Concomitant bacterial infection should be treated with appropriate antimicrobial agents.

Patients should be examined at 2 and 4 weeks following treatment, which allows the original lesions to heal and any remaining eggs to hatch.

Itching can be relieved by the use of over-the-counter oral antihistamines such as diphenhydramine hydrochloride or prescription hydroxyzine hydrochloride.

PREVENTION AND CONTROL MEASURES

Because of the high risk of transmission, the diagnosis of scabies should be considered in any patient with a pruritic cutaneous eruption, especially involving hands, wrists, and elbows. Patients in a hospital or other healthcare facility should be placed in Contact Precautions until 24 hours after treatment. In

persons with crusted scabies, the duration of isolation time is often longer, with some authorities recommending that precautions remain in place for at least 4 days after treatment.[4]

Environmental fomites have been well documented as a source of transmission in many scabies outbreaks. Live mites have been recovered from bed linens, chairs, and the floor surrounding the infested patient's bed. Shared walking belts, skin creams, and lotions have also been shown to be a means of transmission. Clothing and linens should be washed by machine in the hot cycle for at least 10 minutes (50°C or 122°F), then tumbled in a hot dryer for 20 minutes or bagged for 10 days. Placing inanimate objects in a freezer for several days can also kill mites. It is usually not necessary to clean outerwear or furniture because they do not typically come into prolonged direct contact with infested areas. Small disposable items such as creams and lotions should be discarded because of the risk of transmission.

Because scabies transmission can occur during the lengthy egg incubation period, household members and intimate contacts should be treated preemptively. It may also be prudent to treat asymptomatic HCP who have had close contact with infested patients during such activities as bathing and applying topical lotions or massages.

IMPLICATIONS FOR INSTITUTIONAL SPREAD

Scabies is becoming increasingly more common, particularly among immunocompromised patients and residents of long-term care facilities. High attack rates among HCP may occur when caring for patients with undiagnosed scabies, especially those with crusted lesions. Typical distribution of lesions in HCP includes the forearms, abdomen, and thighs. Infested HCP may spread scabies to other patients or coworkers. Thus, control of a scabies outbreak is typically achieved by treatment of the entire population at risk over the same 24- to 48-hour period, whether or not symptoms are present. All recently used clothing, bed linens, and towels should be washed in the hot cycle or, if necessary, dry cleaned 24 hours after treatment.[20]

Pediculosis

Pediculosis is defined as any type of louse infestation.[1,2,3,4,21,22,23]Lice are visible (2 to 3 mm long)

wingless parasites with three pairs of lateral legs ending in "claws." Three species of lice infest humans: *Pediculus humanus capitis*(head louse), *P. humanus corporis*(body louse), and *Phthirus pubis*(crab or pubic louse); however, there are more than 3000 species of lice (Figure 99-2).

Eggs are laid by the fertilized adult and appear as oval "nits" on hairs or fibers of clothing.

After 7 to 10 days, small nymphs emerge from the eggs and must feed on blood within 24 hours. Nymphs molt three times during the maturation process.

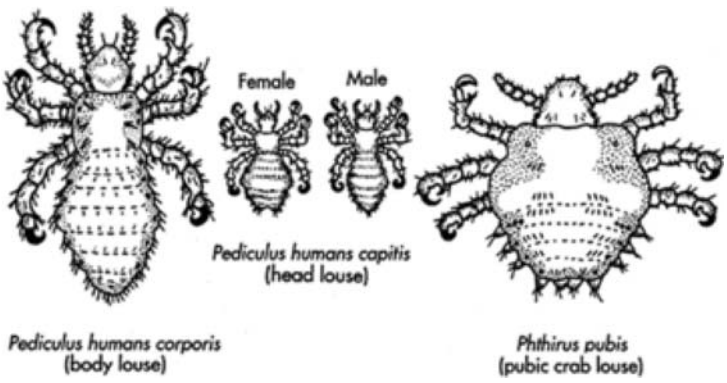

Figure 99-2.

Species of lice that infest humans.

View Image

EPIDEMIOLOGY

Humans are the only natural reservoirs of body, head, and pubic lice. Epidemics of pediculosis still occur and may be associated with poor hygiene, overcrowding, and inadequate facilities for keeping people and clothing clean. There appears to be increasing number of cases among persons of all

socioeconomic levels. Likely contributing factors include communal living, and widespread travel (Table 99-1).[1,2,3,4,21,22,23]

Among school-age children, the closeness of individuals and proximity of their clothing in storage contribute to the spread of head lice. In the United States during 1998, an estimated 12 to 24 million school days were lost because of "no-nit" policies, which exclude children who had any residual nits (egg cases). This exclusion is now considered unnecessary if the child has had proper treatment. Head lice are rare in children of African American descent.[22]

In the past, body lice have been important in the transmission of epidemic typhus (*Rickettsia prowazekii*), relapsing fever (*Borrelia recurrentis*), and trench fever (*Bartonella quintana*)[21]; head lice and pubic lice do not transmit disease.

TRANSMISSION

Head lice are transmitted through direct contact with the louse or contact with personal items such as hats, helmets, headset earphones, brushes, combs, or bedding. Head lice die within 24 to 48 hours after leaving a host.

Body lice are transmitted through direct contact with the louse or through contact with clothing or bedding. The lice cling to clothing, especially seams. With heavy infestation, eggs (nits) may attach to hairs.

Pubic lice are transmitted by direct contact with the louse through close physical contact, especially sexual intercourse. Transmission may also occur via clothing or bedding. Transmission through other inanimate objects (e.g., toilet seats) is extremely rare because of the short life span of lice apart from a human host.

Table 99-1 Characteristics of Lice That Infest Humans

Characteristic	Body and Head Lice	Pubic Lice
Time for incubation of ova	8–9 days	8–9 days
Time from egg to adult	10 days	15 days
Life span of female	30–35 days	35 days
Common site of infection	Head: Especially, back of head, neck, ears axillae, and scalp Body: Shoulders, waist, and areas of clothing contact	Genital region; rarely in eyelashes
Time of survival off host	Head: 2 days Body: 4–7 days	1 day

CLINICAL MANIFESTATIONS

Lice bites cause intense itching and occasionally fever. Bites can be hemorrhagic because of an anticoagulant that is introduced. Excoriated bite sites often become secondarily infected by bacteria, causing impetigo or pyoderma. With head lice, secondary bacterial infection may produce scarring, matted hair, and scalp ulcerations.

DIAGNOSIS

Pediculosis capitis

Few adult lice are typically seen with head lice infestation, but often numerous nits are firmly attached to hair shafts. Nits are initially attached close to skin because eggs cannot hatch at temperatures less than 22°C (71.6°F). Thus nits that are more than 12 mm (0.5 inches) from skin have probably hatched, depending on temperature and humidity conditions. Given that scalp hair grows about 0.5 mm daily, the presence of nits 10 cm or longer away from the scalp indicates the infestation is at least 6 months old. Nits can be differentiated from dandruff or hair casts because they do not slide along hair and can only be removed from the hair shaft using a fine-tooth comb. Infested hair also demonstrates fluorescence under ultraviolet light (Wood's lamp).

Phthirus pubis

Infestation with pubic lice is usually identified by the presence of nits attached to pubic hair. The duration of infestation can be estimated by the distance of the nit from the skin, as hair grows approximately 0.5 inches per month.

Pediculosis corporis

Because body lice are rarely found on the body except when feeding, they are usually identified on clothing.

TREATMENT[1,2,3,4,23,24,25,26,27]

There are four main pediculicide options for treating head lice and pupic lice: pyrethroids, pyrethrins, malathion, and lindane. Pyrethroids, such as permethrin 1 percent cream, are often considered to be the drug of choice because a single dose provides a residual effect lasting several days. This residual protection confers an advantage over lindane; however, pyrethroids may be associated with increased pruritus. Pyrethrins, such as piperonyl butoxide, have few major side effects such as rare cases of corneal damage. Malathion lotion uses an irreversible cholinesterase inhibitor that is a superior ovicide to lindane or pyrethrins. Furthermore, malathion is less toxic than lindane and possesses greater residual activity than lindane shampoo; however, this compound is flammable and has an unpleasant smell. Lindane (1 percent gamma benzene hexachloride) remains widely used, but resistance has been reported, and excessive or prolonged use can lead to convulsions or neurological toxicity. Regardless of which specific topical agent is used, application should be repeated in 1 week to eliminate newly hatched nymphs unless all nits have been removed with a nit comb or hair removal. Eyelid involvement can be treated with 1 percent yellow oxide of mercury ophthalmic ointment or petrolatum ophthalmic ointment. Although ivermectin is active against most types of resistant lice, it is not ovicidal. Thus, ivermectin is primarily used for cases that did not respond to topical therapy and is administered using two oral doses (200 µg/kg) given 10 days apart. Trimethoprim-sulfamethoxazole has been demonstrated to be 80 percent effective against head lice and can be used to treat staphylococcal superinfection.[24,25,26]

Application of pediculicides to patients with body lice is usually not necessary. Patients should be bathed and clothes treated as detailed below.

PREVENTION AND CONTROL

Family members and contacts of patients with pediculosis should be examined methodically for lice and nits. Treatment is only indicated if infestation is detected. The only exception is sexual contacts of patients with pubic lice; these individuals may be treated simultaneously without examination.

Head lice and eggs may be transmitted by fomites (e.g., hair brushes, caps, scarves, and coats); however, eggs cannot hatch in inanimate environments or at room temperature. Potential for fomite spread is greatest for body lice because lice and eggs can survive apart from human hosts longer compared with other lice.

There are several methods for fomite disinfection. The simplest method for clothing or bedding disinfection is washing and drying at relatively high temperature (60°C or 140°F for 5–10 minutes). Heating by ironing or dry cleaning is also an option.

For items that cannot be heated, placing them in a freezer for 12 to 24 hours may be effective. Nonwashable items can also be sealed in a leakproof plastic bag. Items that harbor pubic lice should remain sealed for 7 days, whereas items with head lice should be sealed for 10 to 14 days. Articles with body lice require even longer storage because eggs may survive for up to 30 days.

Isolation of patients can be discontinued after initial treatment and proper disinfection or removal of clothing, bedding, and other contaminated personal items. HCP do not require prophylactic or preemptive treatment unless they demonstrate evidence of infestation. Except for vacuuming and standard cleaning protocols, special cleaning of rooms inhabited by infested patients (e.g., fumigation or use of insecticidal sprays) is not recommended.

Myiasis

Myiasis is defined as human infestation by larvae (maggots) of a large variety of dipterous flies.[1,28,29,30,31,32,33,34,35,36] Eggs are laid by mature female flies on skin, wounds, mouth, nose, and ears. Fly larvae hatch from the eggs and do not multiply before developing into adult flies. Human infestation by larvae varies depending on the fly species. Involvement ranges from superficial, where the larvae are confined to necrotic tissue (e.g., *Musca domestica*, housefly, or blowfly) to burrowing within normal skin (e.g., *Dermatobia hominis*, bot fly, or African tumbu fly).

EPIDEMIOLOGY

Myiasis is more common in warmer tropical climates where cattle and other animals serve as reservoirs for various fly species. In the case of *D. hominis*, mosquitoes act as the reservoir (eggs are laid on the abdomen of mosquitoes) and fly larvae enter at the site of a mosquito bite.

In healthcare, maggots have been used therapeutically to consume devitalized tissue and débride necrotic wounds.[32,33]

Healthcare-associated myiasis often occurs in debilitated patients with necrotic wounds or fecal discharge who are subject to neglected nursing care, especially during summertime. One Midwestern

U.S. intensive care unit outbreak of nasal green blowfly (*Phaenicia sericata*) myiasis was related to a mouse infestation within the hospital.[34]

Ophthalmomyiasis most commonly occurs in North America by infestation of the nasal bot fly larvae (*Oestrus ovis*), especially in the southern United States, including California, Texas, and Hawaii.[35,36]

CLINICAL MANIFESTATIONS

Parasitic (furuncular) myiasis results from larval invasion of unbroken skin or periorificial tissue, producing an abscess-type lesion that may drain purulent material. Larvae burrow into skin, causing dermatitis, and may also migrate to other organs (e.g., ear, nose, eye, brain), causing serious illness or death.

DIAGNOSIS

The diagnosis of myiasis is often recognized when visually inspected by an experienced clinician. However, burrowed lesions may require tissue biopsy. If speciation of fly larvae is desired, formal consultation with an accredited entomologist, the local public health department, or tertiary pathology referral center (e.g., U.S. Armed Forces Institute of Pathology, Washington, DC) is strongly recommended. Fly larvae can be collected and kept alive in a bottle containing moist sand and raw meat until they develop into mature flies. Maggots can also survive on a blood agar culture medium.

TREATMENT

Treatment involves removal of fly larvae. This is often accomplished by covering the wound, which contains the breathing orifice of the insect, with a thick impermeable layer of petrolatum ointment. Liquid paraffin, beeswax, pork fat, or chewing gum has also been used for this purpose. Suffocation will cause the larvae to migrate to the skin surface in search of air. Topical anesthetics (e.g., ethyl chloride spray or lidocaine injection) may be helpful, especially if surgical excision is performed. Application of 10 percent chloroform in vegetable oil can be used for aural myiasis.

PREVENTION

Preventive measures include the use of simple physical barriers to prevent fly entry into the environment (e.g., window screens). Appropriate waste disposal and location of waste receptacles are also important to prevent flying insects from entering patient care areas. Adequate insect control programs using pyrethrin aerosol, other insecticide repellents, or insect extermination lamps may be required in summer months.

Bed Bugs (Cimex lectularius)

Bed bugs are small, reddish brown, flattened, wingless insects (Figure 99-3) that feed solely on the blood of humans and other warm-blooded animals, usually at night. Their saliva causes intense pruritus, which can lead to secondary bacterial infection. Bed bugs grow up to 7 mm in length with a life span ranging from 4 months to 1 year. A female bed bug can lay a total of 200 eggs during its lifetime, usually at a rate of three to four per day after a blood meal. Bed bug eggs are white, measure 0.1 cm in size, and have an adherent coating. The eggs incubate 6 to 17 days before hatching and nymphs undergo five molts before maturing into adults. Each nymphal stage requires a full blood meal. Although *Cimex*spp. bed bugs have been experimentally infected with several viruses under laboratory conditions,

disease transmission to humans has not been clinically demonstrated, as opposed to the *Reduviidae*spp. bed bugs, which transmit Chagas disease in South America.

EPIDEMIOLOGY

Bed bugs became uncommon after World War II as a result of the use of dichlorodiphenyltrichloroethane pesticide in developed countries but have recently reemerged, likely because of increased travel and international trade. They form nests in cracks, furniture seams, bed frames, and mattresses. These insects can survive for several months without feeding and can hide within crevices and other small recessed spaces. These locations include walls, headboards, baseboards, mattress seams, areas of clutter, and undersides of furniture, especially in adjoining apartments, homeless shelters, and hotels. A characteristic finding is small drops of blood on bed sheets or pillows caused by engorged bed bugs that were crushed. Bed bug infestations also emit an odor caused by dark oily excrement.

Figure 99-3.

Bed bug (*Cimex lectularius*). (Provided with permission by Dr. Michael F. Potter of the University of Kentucky, Lexingto

View Image

CLINICAL PRESENTATION

Bed bug bites cause pruritic macules in previously unexposed patients. In patients with repeated bites, there may be papules, urticaria, or bullae resulting from a hypersensitivity reaction.

TREATMENT

Treatment of patients is primarily symptomatic, consisting of anti-inflammatory topical corticosteroid preparations, oral antihistamines, and antibacterial agents for secondary infection. The major intervention is environmental control, with recognition of infestation and use of pesticides such as malathion or pyrethrins. Approved lightly sprayed pesticides should be administered by a licensed exterminator to all places of harbor.

HOSPITAL RESPONSE

Most patients from bed bug-infested dwellings do not carry bed bugs on their body or clothing. Because these insects have not been proven to transmit serious disease and are not easily spread, they are mainly an environmental pest control issue rather than an infection prevention problem. If decontamination of infested articles is desired, bagging and heating them to 120°F for at least 10 to 20 minutes is more effective than attempting to freeze items, which requires several days to be successful.

Important Pathogenic Protozoa

The reader is encouraged to access information on these parasites from the Centers for Disease Control and Prevention or public health websites (see Supplemental Resources).

Protozoa are single-celled amoebae, flagellates, ciliates, and tissue-dwelling organisms. A large variety of protozoa exists, but most are not pathogenic to humans.[20] Infections with parasitic protozoa are typically not related to infection prevention activities in hospitals. However, some of them have important public health considerations in terms of both the organism and of vectors or sources.

EPIDEMIOLOGY

Protozoa are typically divided into groups depending on their method of transmission.

Water- or foodborne:

- *Entamoeba histolytica:* amoebiasis (intestinal or disseminated); worldwide; higher prevalence in areas with poor sanitation
- *Blastocystis hominis:* intestinal infection; worldwide distribution
- *Dientamoeba fragilis:* intestinal parasite, often asymptomatic but may cause disease; worldwide
- *Cryptosporidium parvum:* cryptosporidiosis causing intestinal, biliary, or respiratory tract disease; worldwide; reservoir is human and cattle and contaminated water sources are often implicated in outbreaks
- *Cyclospora cayetanensis:* cyclosporiasis intestinal infection; worldwide
- *Giardia lamblia*: giardiasis intestinal infection; worldwide; reservoir is human and many animal species
- *Isospora belli (also Cystoisospora):* intestinal infection; worldwide (mainly tropical and subtropical locales)
- *Acanthamoeba* spp.: may cause serious infections of the eye (*Acanthamoeba keratitis*), brain, and spinal cord in immunocompromised people (granulomatous amebic encephalitis), and disseminated infection in persons with a compromised immune system; worldwide; contaminated water sources, including pools or hot tubs, soil, air (in association with cooling towers, heating, ventilation and air conditioner systems), sewage systems, and drinking water systems (shower heads, taps)
- *Naegleria fowleri:* causes very rare but severe brain infection; worldwide; reservoir is warm freshwater and soil

Insectborne:

- *Plasmodium* spp.: causes malaria in tropical and subtropical locales; transmitted to humans via bite of *Anopheles* mosquito; reservoir is humans, possibly other primates
- *Trypanosoma* spp.: causes African sleeping sickness (tropical Africa) transmitted by *Glossina* (tsetse) fly and Chagas disease (Central and South America) transmitted by blood-sucking species of Reduviidae (e.g., kissing bug, cone-nose bug); reservoir is mainly humans, and possibly domestic and wild animals
- *Babesia* spp.: causes babesiosis worldwide; transmitted by *Ixodes* ticks; reservoir is deer mice or other small mammals
- *Leishmania* spp.: causes leishmaniasis or kala azar worldwide; transmitted by sandflies; reservoir is humans and many animal species, including wild and domestic Canidae (foxes, dogs); some marsupials

Animalborne:

- *Toxoplasma gondii:*toxoplasmosis foodborne illness; worldwide; generally not serious except when infection occurs during pregnancy (maternal to fetal transmission) or in immunocompromised people; cats are an important reservoir (become infected after eating small animals and birds)

Sexually transmitted:

- *Trichomonas vaginalis:*trichomoniasis sexually transmitted infection; worldwide

Important Pathogenic Worms: Classification

Intestinal roundworms (nematodes):

- *Ascaris lumbricoides:*ascariasis; tropic and subtropical locales; reservoir is humans, pigs (different species)
- *Enterobius vermicularis:*pinworm; worldwide
- *Trichuris trichiura:*whipworm; worldwide
- *Necator americanus:*hookworm; worldwide
- *Ancylostoma duodenale:*hookworm; worldwide
- *Strongyloides stercoralis:*mainly tropical and subtropical locales
- *Capillaria philippinensis:*capillariasis; endemic in the Philippines, also occurs in Thailand. Rare cases reported from other countries.

Tissue roundworms:

- *Wucheria bancrofti:*a cause of elephantiasis (lymphatic filariasis); tropics and subtropics; vector is various mosquito species
- *Brugia*spp.: a cause of elephantiasis (lymphatic filariasis); tropics and subtropics; vector is various mosquito species
- *Onchocerca*spp.: cause of river blindness; transmitted by black fly
- *Dirofilaria immitis:*dog heartworm
- *Loa loa:*African eye roundworm
- *Trichinella spiralis:*trichinosis or trichinellosis; worldwide; ingestion of infected meat, including domestic pig and wild animals
- *Angiostrongylus cantonensis*

Intestinal tapeworms (cestodes):

- *Taenia*spp.: worldwide; raw or undercooked meat
- *Diphyllobothrium latum:*worldwide; fish tapeworm
- *Hymenolepis nana:*dwarf and rat tapeworm; worldwide; rodent, and humans

Tissue tapeworms:

- *Echinococcus*spp.: worldwide; hydatid cysts in tissues

Intestinal flukes (trematodes):

- *Clonorchis sinensis:*liver fluke
- *Fasciola hepatica:*common liver or sheep liver fluke
- *Fasciolopsis buski:*giant fluke of Southeast Asia
- *Paragonimus westermani:*lung fluke, worldwide

Tissue flukes:

- *Schistosoma*spp.: blood or snail fluke, tropical regions, snail is intermediate host

Information sheets on some of the most significant parasites are located on the CDC website at **http://www.cdc.gov/parasites/az/**.

Conclusions

Although a variety of human parasites exist, relatively few have direct impact on infection preventionists. Ectoparasites may be spread through direct or indirect contact with infested persons or fomites. Outbreaks of ectoparasites have been well documented in a variety of healthcare and institutional settings.

Future Trends

As the number of immunocompromised patients increases, the risk of serious parasitic or ectoparasitic disease often rises. Although effective treatments exist, resistance has been documented. Additionally, many treatments are associated with side effects and can cause additional problems. Efforts should be directed toward improving available treatments and reducing risk of transmission.

International Perspective

Ectoparasites are seen around the world. This is in contrast to most parasitic protozoa and parasitic worms (nematodes, trematodes, and cestodes), which are mostly seen outside the United States and other developed countries. In resource-constrained countries, many human parasites are transmitted through contaminated water sources or food products. However, given the increasing modern global travel, more patients with parasitic diseases have been seen in healthcare systems worldwide.

Section 9

Infection Prevention for Occupational Health

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Occupational Health

Author(s): Sue Sebazco, RN, MBA, CIC
Director of Infection Control and Employee Health & Education

Texas Health
Arlington, TX

Published: October 3, 2014

Abstract

This chapter outlines the infection prevention considerations when designing and implementing an occupational health program for a healthcare facility. The content includes objectives for an occupational health program along with the major components. The risk for transmission of infections between healthcare personnel and patients is discussed. Guidelines for work restrictions for healthcare personnel with infectious diseases and exposure management are provided. There are suggestions for measuring improvement in the prevention of occupational injuries and exposures. The chapter also includes a description of workers' compensation.

Key Concepts

- An occupational health program is an essential and cornerstone element in efforts to provide a safe environment for patients and healthcare personnel.
- Elements of an occupational health program include surveillance, education, immunization, and injury prevention and response.
- Transmission of infection to and from healthcare personnel is a recognized risk and the infection preventionist must work collaboratively with the occupational health provider.
- The occupational health program and infection preventionist work collaboratively to implement pre-exposure vaccination programs, particularly those that are required annually, postexposure intervention responses, and other program activities to prevent exposure to infection diseases.
- Because there are a number of common infectious processes with no indications for postexposure intervention, an occupational health program must be structured so patients and healthcare personnel are actively protected.

- Work restrictions in the healthcare facility related to communicable diseases must be clearly outlined in policy and enforcement/accountability methods built in to the process.
- Performance measurements must be developed so that exposure opportunities are limited for patients, visitors, and healthcare personnel.
- The infection preventionist should be familiar with workers' compensation law and application in the occupational health program.

Background

Healthcare organizations need to provide a safe environment for both patients and healthcare personnel (HCP). During the past four decades there has been an increased awareness of occupational hazards to HCP. Regulatory and licensing agencies are also aware of the need to address the prevention of hazards in the healthcare workplace. An infection preventionist (IP) has a vital role within the organization in identifying risk of communicable diseases to the patient and HCP, assessing the potential adverse outcomes, implementing pre-exposure and postexposure policies and procedures, and evaluating the effectiveness of measures taken. To carry out this function effectively, the IP needs an occupational health policy (OHP) that is based on valid, evidence-based strategies. Recommended practices need to be based on the epidemiology of infectious disease transmission in the healthcare facility, targeting the HCP as a potential source or host. The organization needs to analyze what elements should be included in its facility's OHP by recognizing the characteristics of the patient, client, or resident population served, as well as those of the HCP. The type of facility, the services provided, the geographical location, and the diseases that are endemic in the community populations served also influence the elements that need to be included.

An organizational structure may not formally include the IP as a member of the OHP. However, the IP of a healthcare organization is often called on to participate when infection prevention issues for HCP need to be addressed. Often the IP is asked to provide credible references to support the policies and practices that are in place.

The OHP uses a process improvement approach directed by a risk assessment to develop appropriate policies and procedures. Working collaboratively with the OHP staff, the IP provides input to the risk assessment by providing feedback on infection prevention practices. Results of infection prevention compliance observations reported by the IPs often identify trends that affect HCP safety and provide opportunities for improvement.

Basic Principles

Infection prevention policies, procedures, and practices in an OHP are designed to interrupt the transmission of infection between the HCP and patients. Some infectious processes that present a possible threat to HCP may be prevented with administration of pre-exposure immunizations. Other infectious processes caused by communicable diseases may have specific indications for postexposure interventions. Yet, some infectious processes may be prevented primarily by prevention strategies.

The Centers for Disease Control and Prevention (CDC) defines the term *HCP* as all paid and unpaid persons working in healthcare settings who have the potential for exposure to infectious materials, including body substances, contaminated medical supplies and equipment, contaminated environmental surfaces, or contaminated air.[1]Health Canada's Centre for Infectious Disease Prevention refers to

healthcare worker as any individual who has the potential to acquire or transmit infectious agents during the course of his or her work in healthcare.[2] These terms include nurses, nursing assistants, physicians, technicians, therapists, pharmacists, students and trainees, contractual staff not employed by the healthcare facility, emergency medical service personnel, dental personnel, laboratory personnel, autopsy personnel, researchers, and volunteers who have direct patient care. Persons not directly involved in patient care but potentially exposed to infectious agents (e.g., clerical, dietary, housekeeping, maintenance, and volunteers) are also to be included as HCP or healthcare workers.

Healthcare is delivered not only in acute care hospitals and long-term care facilities, but also in freestanding surgical and outpatient centers, emergency care clinics, persons' homes, and during prehospital emergency care. HCP in any setting may acquire infections from or transmit infections to persons to whom they provide care, other personnel, household members, or other community contacts.

The healthcare organization's administration, medical staff, and other HCP need to support the infection prevention objectives of an OHP. These objectives are to (1) educate HCP about the principles of infection prevention and their individual responsibility for infection prevention, (2) collaborate with the infection prevention and control department in monitoring and investigating potentially harmful infectious exposures and outbreaks, (3) provide care to personnel for work-related illnesses or exposures, (4) identify work-related infection risks and institute appropriate preventive measures, and (5) contain costs by preventing infectious diseases that result in absenteeism and disability.[1]

There are elements that should be included when designing an occupational health service for HCP.[1] The IP may be involved in many of these functions. These include the following.

- Collaboration or oversight by a licensed healthcare provider responsible for the medical orders for pre-exposure vaccination, medical health screening, and postexposure treatment.
- Coordination with other departments that support the infection prevention objectives can ensure surveillance for infection in personnel and assist with exposure investigation and implementation of preventive measures.
- Medical evaluations performed before placement can ensure that personnel will not pose a risk for infection transmission. Additionally, information gathered through this evaluation may lead to identifying personnel who may be at increased risk for infection and whose placement may need to be considered carefully. It has not been demonstrated that a physical examination is cost effective for infection prevention purposes. Periodic evaluations may need to be performed for job assignments or work-related problems.
- Personnel health and safety education can contribute to the workers' compliance with infection prevention practices through understanding of the rationale. Federal, state, and local regulations may exist in regard to requirements for employee education and training. Items to be considered are risks for a job category, preventive measures, and educational materials that are appropriate in content, vocabulary, and language.
- Immunization programs provide protection from vaccine-preventable diseases for both HCP and those under their care. Vaccine preventable infectious diseases include Hepatitis A and B, influenza, measles, mumps, rubella, tetanus, pertussis, and varicella-zoster (chickenpox). The U.S. Public Health Service's Advisory Committee on Immunization Practices (ACIP) addresses recommended immunization practices. For vaccinations recommended for HCP see Table 100-1. Immunizations are discussed further in **103. Immunization of Healthcare Personnel**.

- Management of job-related illnesses and exposures should also be provided for the HCP. Postexposure follow-up, medical surveillance, and reporting are mandated by regulatory agencies.
- Work restrictions may be indicated for workers who present with illnesses that may be transmitted in the workplace. See Table 100-2 for a summary of suggested work restrictions.[1]The facility should have a policy in place that identifies who has the authority to remove personnel from duty.
- Health counseling to provide targeted information about the risk for and prevention of occupationally acquired infections should be available to personnel. Personnel may need to be reassured regarding an exposure and educated on the risks for acquiring an infection and benefits of postexposure prophylaxis regimens. Personnel also must be educated to report a community exposure to a communicable infectious disease.
- Maintenance of records, data management, and confidentiality are major requirements by federal, state, and local standards of the OHP. A computerized personnel database is preferred. Copies of individual records are to be made available to personnel on request.

Table 100-1 Immunization Schedule for Healthcare Personnel

Vaccine	Indication	Schedule
Hepatitis A	Laboratory and primate worker	1 mL intramuscularly at 0, 6 months
Hepatitis B	Occupational exposure to blood, blood products, or bodily secretions	Three doses of 1 mL intramuscularly at 0, 1, and 6 to 12 months
Hepatitis A and B	As for Hepatitis A and Hepatitis B	1 mL intramuscularly at 0, 1, and 6 months
Influenza	Persons attending high-risk patients (e.g., elderly, other) Inactivated vaccine FluMist	One dose of 0.5 mL intramuscularly annually Intranasal dose of 0.2 mL annually (split between both nostrils)
MMR Measles Mumps Rubella	Adults born after 1957 without a history of physician-diagnosed measles, serological immunity, or documentation of having received two doses of vaccine Adults born after 1957 without a history of physician-diagnosed measles, serological immunity, or documentation of having received two doses of vaccine Unimmunized women of childbearing age and healthcare personnel	0.5 mL subcutaneously at 0, and at least 1 month later 0.5 mL subcutaneously once 0.5 mL subcutaneously once
Polio	Laboratory and other healthcare personnel who come in contact with the live virus	Three doses of 0.5 mL subcutaneously. First two doses separated by 4 to 8 weeks, and a third dose 6 to 12 months after the second dose.

Td	Persons without a history, or an unknown history of Td immunization or >10 years since last dose	Unimmunized: 3 doses of 0.5 mL intramuscularly at 0, 1 to 2, 6 months Booster: 1 dose every 10 years
Tdap	Healthcare personnel with direct patient contact, healthy adults 19 to 64; close contacts of those (<1 year Td dose)	0.5 mL intramuscularly one-time dose (can be substituted for any)
Varicella	Adults nonimmune to varicella	0.5 mL subcutaneously at time 0 weeks and 4 to 8 weeks later

OCCUPATIONAL HEALTH HAZARDS

Postexposure Interventions

Some infectious processes present a possible threat to HCP and have specific indications for postexposure intervention. Figure 100-1 provides an algorithm for assessment of occupational exposure and when to implement an intervention.

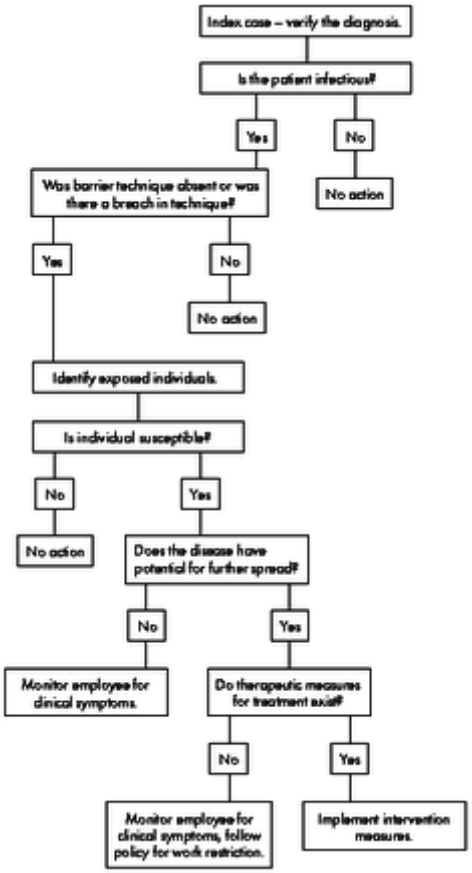

Figure 100-1.

Algorithm for management of healthcare worker e View Image

Tuberculosis

The CDC publishes recommendations on controlling the spread of tuberculosis (TB) in healthcare facilities.[3]The Occupational Health and Safety Administration (OSHA) has a compliance directive addressing occupational exposure to TB in healthcare facilities, where the CDC has identified TB transmission to be at high risk.[4]

This was written as a directive to their field offices to clarify the application of the General Duty Clause when inspecting facilities identified as belonging in these high-hazard groups. OSHA's General Duty Clause requires each employer to provide its employees a place of employment free from recognized hazards.[5]

An unidentified case of pulmonary or laryngeal TB can be a source of unprotected exposure to HCP. Personnel should be educated about TB, how it is spread, its signs and symptoms, and preventive measures.

The facility's annual TB risk assessment will determine the types of administrative, environmental, and respiratory controls that are appropriate to the setting. The three TB screening risk

classifications are low risk, medium risk, and potential ongoing transmission. The TB screening risk classification, along with the facility's state regulations, directs how often tuberculin skin testing (TST) is required and for which HCP. See **95. Tuberculosis and Other Mycobacteria**, for additional information on TB risk assessments. A TB screening program should include part-time, temporary, contract, and full-time HCP. HCP who have duties that involve face-to-face contact with patients with suspected or confirmed TB disease, as well as those involved in the following, should also be included:[3]

1. Entering patient rooms or treatment rooms, whether or not a patient is present.
2. Participating in aerosol-generating or aerosol-producing procedures.
3. Participating in suspected or confirmed *Mycobacterium tuberculosis* specimen processing.
4. Installing, maintaining, or replacing environmental control in areas in which persons with TB are encountered.

Latent TB infection (LTBI) refers to a condition that occurs after initial infection with *Mycobacterium tuberculosis (M. tuberculosis)*. Within 2 to 12 weeks after the initial infection, the immune response limits additional multiplication of the tubercle bacilli and test results for *M. tuberculosis* infection become positive. Certain bacilli remain in the body and viable for multiple years. These persons are asymptomatic and not infectious.[3]

Table 100-2 Summary of Suggested Work Restrictions for HCP Exposed to or Infected With Infectious Diseases of Importance in Healthcare Settings, in the Absence of State and Local Regulations (Modified from ACIP Recommendations)

Disease/Problem	Work Restriction	Duration	Category
Conjunctivitis	Restrict from patient contact and contact with the patient's environment	Until discharge ceases	II
Cytomegalovirus infections	No restriction		II
Diarrheal diseases Acute stage (diarrhea with other symptoms) Convalescent stage, *Salmonella*spp.	Restrict from patient contact, contact with the patient's environment, or food handling Restrict from care of high-risk patients	Until symptoms resolve Until symptoms resolve; consult with local and state health authorities regarding need for negative stool cultures	IB IB
Diphtheria	Exclude from duty	Until antimicrobial therapy completed and two cultures obtained 24 hours apart are negative	IB
Enteroviral infections	Restrict from care of infants, neonates, and immunocompromised patients and their environments	Until symptoms resolve	II
Hepatitis A	Restrict from patient contact, contact with patient's environment, and food handling	Until 7 days after onset of jaundice	IB

Hepatitis B Personnel with acute or chronic Hepatitis B surface antigenemia who do not perform exposure-prone procedures Personnel with acute or chronic Hepatitis B e antigenemia who perform exposure-prone procedures	No restriction*; refer to state regulations; Standard Precautions should always be observed Do not perform exposure-prone invasive procedures until counsel from an expert review panel has been sought; panel should review and recommend procedures the worker can perform, taking into account specific procedure as well as skill and technique of worker; refer to state regulations	Until Hepatitis B e antigen is negative	II II
Hepatitis C	No recommendation	Until lesions heal	Unresolved issue
Herpes simplex Genital Hands (herpetic whitlow) Orofacial	No restriction Restrict from patient contact and contact with the patient's environment Evaluate for need to restrict from care of high-risk patients		II IA II
Human immunodeficiency virus	Do not perform exposure-prone invasive procedures until counsel from an expert review panel has been sought; panel should review and recommend procedures the worker can perform, taking into account specific procedure as well as skill and technique of the worker; Standard Precautions should always be observed; refer to state regulations		II
Measles Active Postexposure (susceptible personnel)	Exclude from duty Exclude from duty	Until 7 days after the rash appears From 5th day after first exposure through 21st day after last exposure and/or 4 days after rash appears	IA IB
Meningococcal infections	Exclude from duty	Until 24 hours after start of effective therapy	IA
Mumps Active Postexposure (susceptible personnel)	Exclude from duty Exclude from duty	Until 9 days after onset of parotitis From 9th day after first exposure through 26th day after last exposure or until 9 days after onset of parotitis	IB II
Pediculosis	Restrict from patient contact	Until treated and observed to be free of adult and immature lice	IB

Pertussis	Exclude from duty	From beginning of catarrhal stage through third week after onset of paroxysms or until 5 days after start of effective antimicrobial therapy	IB
Active	No restriction, prophylaxis recommended		II
Postexposure (asymptomatic personnel)	Exclude from duty		IB
Postexposure (symptomatic personnel)		Until 5 days after start of effective antimicrobial therapy	
Rubella	Exclude from duty	Until 5 days after rash appears	IA
Active	Exclude from duty		IB
Postexposure (susceptible personnel)		From 7th day after first exposure through 21st day after last exposure	
Scabies	Restrict from patient contact	Until cleared by medical evaluation	IB
*Staphylococcus aureus*infection	Restrict from contact with patients and patients' environment or food handling	Until lesions have resolved	IB
Active, draining skin lesions	No restriction, unless personnel are epidemiologically linked to transmission of the organism		IB
Carrier state			
Streptococcal infection, group A	Restrict from patient care, contact with patient's environment, or food handling	Until 24 hours after adequate treatment started	IB
Tuberculosis	Exclude from duty	Until proved noninfectious	IA
Active disease	No restriction		IA
PPD converter			
Varicella	Exclude from duty	Until all lesions dry and crust	IA
Active	Exclude from duty		IA
Postexposure (susceptible personnel)		From 10th day after first exposure through 21st day (28th day if VZIG given) after last exposure	

Zoster Localized, in healthy person Generalized or localized in immunosuppressed person Postexposure (susceptible personnel)	Cover lesions; restrict from care of high-risk patient[†] Restrict from patient contact Restrict from patient contact	Until all lesions dry and crust Until all lesions dry and crust From 10th day after first exposure through 21st day (28th day if VZIG given) after last exposure or, if varicella occurs, until all lesions dry and crust	II IB IA
Viral respiratory infections, acute febrile	Consider excluding from the care of high-risk patients[‡]or contact with their environment during community outbreak of RSV and influenza	Until acute symptoms resolve	IB

*Unless epidemiologically linked to transmission of infection.

[†]Those susceptible to varicella and who are at increased risk of complications of varicella, such as neonates and immunocompromised persons of any age.

[‡]High-risk patients as defined by the ACIP for complications of influenza.

From Centers for Disease Control and Prevention. Guidelines for infection control in the healthcare worker, 1998. *Am J Infect Control*1998;26:289–354.

The purified protein derivative (PPD)-based TST has been used in the United States to diagnose LTBI. There are *in vitro*cytokine-based immunoassays for the detection of *M. tuberculosis* infection. These tests measure cell-mediated immune responses to peptides from two *M. tuberculosis* proteins that are not present in any bacille Calmette-Guérin (BCG) vaccine strain and are absent from the majority of nontuberculosis *Mycobacteria*. One such blood assay for *M. tuberculosis*(BAMT) is the QuantiFERON-TB Gold test (QFT-G). Additional cytokine-based immunoassays are under development. Specific guidelines regarding use of QFT-G as part of an OHP are provided by the CDC.[6]

A TB control program should be developed according to the most current CDC recommendations. The program should be designed according to the results of the risk assessment that includes the TB experience in the facility and whether or not the facility will be or has the capability of providing care to persons with TB.

A TST should be administered, read, and interpreted by trained personnel. Use the intradermal (Mantoux) method to administer the PPD-based TST. Tine tests should not be used. Baseline screening should be conducted at the time of hire. Those individuals who have a history of having received the BCG vaccination should be included unless they have documentation of a previous positive reaction. A two-step TST should be performed when the initial TST is negative and there is no documented negative TST during the preceding 12 months. Interpretation of the TST depends on measured TST induration in millimeters, the person's risk for being infected with *M. tuberculosis*, and risk for progression to active TB if infected. Interpret the TST test according to the CDC guidelines. See Table 100-3 for information regarding results of TST and QFT tests. The frequency of periodic follow-up TST tests is based on the facility's risk assessment. Exempt those employees who have a positive baseline TST or have had adequate treatment for TB.

Table 100-3 Interpretations of Tuberculin Skin Test and QuantiFERON-TB Test Results According to the Purpose of Testing for

Purpose of Testing	Tuberculin Skin Test	QuantiFERON-TB Test
Baseline	≥10 mm is considered a positive result (either first or second step)	Positive (only one-step)
Serial testing without known exposure	Increase of ≥10 mm is considered a positive result (TST conversion)	Change from negative to positive (QFT conversion)
Known exposure (close contact)	≥5 mm is considered a positive result in persons who have a baseline TST result of 0 mm; an increase of ≥10 mm is considered a positive result in persons with a negative baseline TST result or previous follow-up screening TST result of ≥0 mm	Change to positive

From Centers for Disease Control and Prevention. Guidelines for preventing the transmission of *Mycobacterium tuberculosis*in health-care settings, 2005. *MMWRRecomm Rep*2005;54(RR-17):1–144.

If personnel have a positive TST, a chest radiograph should be done promptly to check for active disease. A history of exposure should be obtained to determine if infection is occupational or community-associated. The person should be instructed to report symptoms that are suggestive of TB. Chest radiographs do not need to be repeated unless the person is symptomatic. However, there may be some state or local regulations that require periodic chest radiographs for personnel with a documented positive TST. If a person is a recent converter, the person should be referred to a healthcare provider for consideration of preventive therapy.

Anergy is a condition in which a person has diminished ability to exhibit delayed T-cell hypersensitivity to antigens because of a condition or situation resulting in altered immune function. An inability to react to a skin test is called cutaneous anergy. In the past, skin tests for anergy were used in conjunction with TSTs for screening programs for *M. tuberculosis* among the immune-compromised and human immunodeficiency virus (HIV)-infected persons. Anergy testing is no longer recommended because it has been found to have poor predictive value.[7]

If there has been unprotected exposure of workers to TB, TSTs should be administered at the time of the exposure and repeated at 12 weeks postexposure to look for possible converters. Chest radiographs

are performed only on those with prior positive TST and who are currently symptomatic. Consider retesting immunocompromised personnel at least every 6 months.[3]

Personnel who have laryngeal or pulmonary TB are excluded from work until they are receiving adequate therapy, the cough has resolved, and there have been three consecutive sputum smears negative for acid-fast bacilli. The occupational health department should obtain periodic documentation from the healthcare provider. If treatment is discontinued, the person needs to be promptly evaluated for infectiousness.

Immunocompromised personnel should be counseled regarding potential risks associated with caring for persons with TB. It may be necessary to offer reasonable accommodations for the work setting.

The *M. tuberculosis* infection conversion rate should be a component of the facility's risk assessment. A TST conversion is a 10-mm or greater increase in the size of the TST induration during a 2-year period in a person with a documented negative (<10 mm) baseline two-step TST result or a person who is not an HCP with a negative (<10 mm) TST result within 2 years. The conversion rate is the percentage of persons whose test result for *M. tuberculosis* infection has converted within a specified period. To calculate a conversion rate, divide the number of conversions among personnel in the setting in a specified period (numerator) by the number of personnel who received tests in the setting over the same period and multiply by 100.

Respiratory Protection Program

The generally accepted respiratory protection that is used to protect personnel from a person with suspected or confirmed TB is a particulate N95 respirator, a requirement identified in OSHA's respiratory protection standard. The standard requires the employer to designate a program administrator who is qualified by appropriate training or experience that is commensurate with the complexity of the program to administer or oversee the respiratory protection program and conduct the required evaluations of program effectiveness. The employer also needs to provide respirators, training, and medical evaluations at no cost to the employee. Furthermore, the employer is required to have a sufficient number of respirator models and sizes so that the respirator is acceptable to, and correctly fits, the user.[8,9]OSHA's standard requires that each person assigned to wear a respirator must receive a fit test before the person is required to wear the respirator in the workplace. After fit testing, the HCP must perform a seal check with each use. A user seal check is an action conducted by the respirator user to determine if the respirator is properly seated to the face. The fit test needs to be repeated annually or whenever respirator design or facial changes, such as in extreme weight loss or gain, occur that could affect the proper fit of the respirator.

A qualitative fit test (QLFT) is one that results in a pass or fail fit test and one that assesses the adequacy of respirator fit that relies on the individual's response to the test agent.

A quantitative fit test (QNFT) is an assessment of the adequacy of respirator fit by numerically measuring the amount of leakage into the respirator. A user seal check is an action conducted by the respirator user to determine if the respirator is properly seated to the face.

A powered air-purifying respirator (PAPR) is an air-purifying respirator that uses a blower to force the ambient air through air-purifying elements to the inlet covering. A fit test is not required.[9]

OSHA requires an employer to establish and implement a written respiratory protection program with worksite-specific procedures. The program is to be updated as necessary and should include

procedures for selecting respirators for use in the workplace; medical evaluations of employees required to use respirators; fit testing procedures; and procedures for proper use, storing, and discarding of respirators. The plan should outline training that includes the respiratory hazards to which the employees are potentially exposed during routine and emergency situations. The proper use of respirators, including putting on and removing them, any limitations on their use, and their maintenance, should also be covered. There should be procedures for regularly evaluating the effectiveness of the program.[9]

In situations in which respirator use is not required and employees request a respirator, employers may provide respirators or permit employees to use their own. However, in such cases, the employer should determine if wearing a respirator would in itself create a hazard. The employer needs to provide the required information for employees using respirators when not required under the standard. In addition, the employer must establish and implement those elements of a written respiratory protection program necessary to ensure that any employee using a respirator voluntarily is medically able to use that respirator, and that the respirator is cleaned, stored, and maintained so that its use does not present a health hazard to the user.

Bloodborne Pathogens

The very nature of a healthcare setting will require contact between HCP and the persons they serve. One of the areas of concern for personnel is bloodborne pathogens (BBP) exposures. There are many ways to prevent transmission. These include promoting the Hepatitis B vaccination for personnel who have contact with blood, considering all patients as a potential source of infection, using appropriate barriers when performing tasks that require contact with blood, and preventing percutaneous injuries. Despite the evolution of a safer work environment in the past few decades, occupational exposures do occur. Management of occupational exposures to Hepatitis B virus (HBV), Hepatitis C virus (HCV), and HIV are outlined in the updated U.S. Public Health Service guidelines[9] and covered in **101. Occupational Exposure to Bloodborne Pathogens**.

An OHP in a healthcare setting should include the following elements of an effective postexposure management program: clearly stated policies and procedures that address confidentiality of exposed and source persons and how to manage the exposure; education and training of workers to alleviate misconceptions and fears; and resources for rapid access to clinical care, postexposure prophylaxis (PEP), and testing of the source person and worker. An assessment of the injury may identify ways to prevent future injuries.

OSHA's BBP standard provides directives for employers to develop an exposure plan that includes providing the Hepatitis B vaccine to employees within 10 days of employment. The standard also requires the employer to provide training on potential hazards, personal protective equipment (PPE), engineering controls, and work practices before the employee's initial assignment. An element of the revision to OSHA's BBP rule in 2001 was the need to maintain a sharps injury log.[10,11,12] The log needs to protect the privacy of the injured worker and include the identification of the device, location of the incident, circumstances surrounding the incident, the procedure being performed, the body part affected, and the objects or substances involved. Another 2001 revision to the standard was the requirement of the documentation of annual consideration and implementation of appropriate engineering controls and solicitation of non-managerial HCP in evaluating and choosing safe medical devices. The exposure control plan should also be reviewed and updated annually.

Hepatitis B Virus

The Hepatitis B vaccination has contributed to the significant decrease of HBV among HCP.[13] At the time of hire, HCP's potential for exposure should be determined and their vaccine status assessed. Post-vaccine screening is advised for personnel at ongoing risk for blood exposure to determine whether response to the vaccine has occurred and to determine the need for revaccination. Revaccinate nonresponders with an additional three-dose series and retest. If the worker is still a nonresponder, then test for Hepatitis B surface antigen (HBSAg) to make sure the worker does not have chronic antigemia. Nonresponders in chronic dialysis centers who do not respond for HBSAg and Hepatitis B surface antibody (anti-HBs) should be tested every 6 months. Risk factors for nonresponse include age, smoking, obesity, immunosuppression, renal failure, and a family history of nonresponse. [14]

An exposure to HBV is defined as the source person being HBSAg positive or the person's status being unknown. If the exposed person is vaccinated, but the vaccine response is unknown, then perform a baseline test for anti-HBs. Baseline testing is not necessary if the exposed person has not been vaccinated or the vaccine response is known. If the exposed person has not been vaccinated, begin the vaccine series at the time of the exposure and administer Hepatitis B immune globulin (HBIG) as soon as possible after the exposure, preferably within 24 hours.

One of the frequently asked questions is whether or not booster doses of the Hepatitis B vaccine are necessary. The current response is no. Maintenance of anti-HBs above 10 mIU/mL is not necessary. It is believed that the majority of responders will show an anamnestic response to vaccine challenge.

Hepatitis C Virus

The average risk for transmission of HCV following a percutaneous exposure is 1.8 percent. Transmission rarely occurs from mucosal contact with HCV-infected blood. There has been no transmission reported to personnel from intact or nonintact skin exposures to blood.[14] Recommendations for follow-up of occupational HCV exposures are discussed in **101. Occupational Exposure to Bloodborne Pathogens**.

A worker who has been exposed to HCV should refrain from donating blood, plasma, organs, tissue, or semen. There is no need for modification of sexual practices, refraining from becoming pregnant, or special precautions to prevent secondary transmission. There are no existing recommendations regarding restricting the professional activities of HCP with HCV infection. However, discussion following a report of surgeon-to-patient transmission suggested that limitations, if any, should be determined on a case-by-case basis after consideration of factors that influence transmission. These considerations should include the provider's inability or unwillingness to comply with infection control standards.[14]

Human Immunodeficiency Virus

The CDC followed HCP who sustained an exposure incident from an HIV-positive source through June 2001. There were 57 HCP who had documented occupationally acquired immune deficiency syndrome (AIDS)/HIV. A case-control study identified risks for transmission.[10] The risk factors identified were: (1) a deep injury from a device with visible blood, (2) the device was from the source person's vein or artery, and (3) the source person died of AIDS within 60 days after the exposure incident.

The average risk for transmission of HIV by the exposure type is 0.3 percent for percutaneous, 0.1 percent for mucous membrane contact, and less than 0.1 percent for nonintact skin contact.[14]

Immediately following the exposure, the HCP and source person should be tested to establish HIV-AB status. HIV testing of needles or other sharps is not recommended. See **101. Occupational Exposure to Bloodborne Pathogens**, for information regarding postexposure management.

Varicella

Transmission of varicella has been documented from sources from healthcare-associated exposures that have included patients, HCP, and visitors. In adults, a history of varicella is highly predictive of serologic immunity, and most adults who have negative or uncertain histories of varicella are also seropositive. HCP are considered to have immunity if they have laboratory evidence of immunity, a history of clinical diagnosed or verified varicella or zoster, or documentation of age-appropriate vaccination. It is recommended that the varicella vaccine be administered to all HCP without evidence of immunity.[15]

Prevaccination serological screening is often cost effective. Postvaccination testing is not necessary or recommended because assays for vaccine immunity are not adequately sensitive. A small percentage of vaccinated individuals will develop a vaccine rash following the varicella vaccine. The risk for disease transmission from this rash is extremely low. In fact, to date, there have been no documented cases of disease transmission after HCP varicella vaccination.

If an unvaccinated susceptible personnel is exposed to varicella, then exclude the person from duty from the 10th day after exposure through the 21st day after exposure, or until all lesions are dry and crusted if varicella occurs. Serotest vaccinated personnel who are exposed to varicella immediately after exposure to assess the presence of antibody. If seronegative, exclude the person from duty from day 10 through day 21 postexposure. If fever, upper respiratory tract symptoms, or rash develop, then exclude the person from duty.

Consider administering the vaccination for exposed unvaccinated personnel without documented immunity. The efficacy of postexposure vaccination is unknown. Therefore, personnel vaccinated after exposure should be managed as previously recommended for unvaccinated persons.

Varicella-zoster immune globulin (VZIG) has not been recommended for immune-competent personnel. However, its use may be considered for immunocompromised or pregnant workers postexposure. If used, extend the time that the worker is excluded from duty from 21 days to 28 days postexposure.

Meningococcal Disease

Meningococcal disease is caused by a variety of serogroups of *Neisseria meningitides (N. meningitides)*. Healthcare-associated transmission is uncommon. When proper infection prevention precautions are not used, transmission of the pathogen from patient to personnel may occur. This occurs through contact with respiratory secretions of patients who have meningococcemia, meningococcal meningitis, or a lower respiratory tract infection with *N. meningitidis*or through handling laboratory specimens.

Postexposure prophylaxis is advised for persons who have had intensive, unprotected contact with infected patients.[1]Unprotected means without wearing a mask and intensive contact would be mouth-to-mouth resuscitation, endotracheal intubation, endotracheal tube management, or close examination of the oropharynx. Prophylactic therapy should be administered immediately after the unprotected exposure. Current recommended regimens to eradicate carriage are rifampin 600 mg orally every 12 hours for 2 days, a single dose of ciprofloxacin 500 mg orally, or a single dose of ceftriaxone 250 mg intramuscularly. Rifampin and ciprofloxacin are not recommended for pregnant women.

It is currently recommended to offer pre-exposure vaccination to laboratory personnel who handle soluble preparations of *N. meningitidis*.[16]

Measles, Mumps, Rubella

The measles, mumps, rubella (MMR) vaccination should not be administered to pregnant HCP or HCP who might become pregnant within the next 28 days.

Rubella

Because healthcare-associated transmission of rubella has occurred from both male and female personnel to susceptible personnel and patients, ensuring immunity among all HCP is the most effective way to eliminate transmission.[1]Personnel should have documentation of one dose of live rubella vaccine on or after their first birthdays or laboratory evidence of immunity to rubella. A dose of MMR is recommended for those HCP who were born before 1957 and who do not have laboratory evidence of immunity.[17]Exposed personnel not immune to rubella need to be excluded from duty from the 7th day after the first exposure through the 21st day after the last exposure.

Measles

Measles transmission has occurred in healthcare facilities. Data suggest that HCP have a risk for measles 19 times greater than that of the general population.[1]The measles virus is transmitted 3 to 4 days before as well as after the rash appears. In 2005, a measles outbreak of 34 cases was the result from one case imported from Europe. Therefore, it is essential that all personnel have presumptive evidence of immunity to measles. Presumptive evidence of immunity is written documentation of vaccination with two doses of MMR vaccine administered at least 28 days apart, laboratory evidence of immunity, laboratory confirmation of disease, or birth before 1957. The MMR vaccination should be administered to those who cannot provide documentation of these conditions. The measles vaccine should be administered to susceptible HCP who have had contact with a measles patient within 72 hours of the exposure. Personnel who are not immune to measles need to be excluded from duty 5 days after the first exposure to 21 days after the last exposure.[1]

Mumps

Mumps can be spread in a healthcare facility. According to the CDC there are usually 250 to 300 cases of mumps reported in the United States each year. In 2006, more than 5,700 cases were reported as the result of an outbreak that began in Iowa and spread to 11 states. In 2006, the ACIP changed its recommendation for just one dose to two doses, because of the improved efficacy of two doses. Most mumps cases in HCP have been community-associated.[1]Personnel have presumptive evidence of immunity if they have written documentation of vaccination with two doses of MMR vaccine administered at least 28 days apart, laboratory evidence of immunity, laboratory confirmation of disease, or birth before 1957. Two doses of MMR vaccine should be administered to those who lack this documentation. Susceptible personnel who are exposed to mumps need to be excluded from duty the 9th day after the first exposure to the 26th day after the last exposure.[18]

Scabies and Pediculosis

Healthcare-associated transmission of conventional and "Norwegian," or crusted, scabies has occurred in various healthcare settings. It is spread by prolonged skin-to-skin contact with an infested individual. Contact Precautions can reduce spread from patient to personnel. Exposed personnel should be evaluated for signs and symptoms of mite infestation. Appropriate therapy should be provided for confirmed or suspected scabies.

Pediculosis is caused by infestation with any of three species of lice: human head louse, human body louse, and pubic, or crab, louse. Healthcare-associated transmission of head and body lice is unlikely, and healthcare-associated transmission of pubic lice is very unlikely. Pediculosis treatment should be provided for exposed personnel if they have evidence of infestation. Do not routinely offer prophylactic scabicides or pediculicides unless transmission has occurred.

Personnel with either scabies or pediculosis should be excluded from duty until they receive appropriate initial treatment and it is found to be effective.[1]

Pertussis

Pertussis was previously thought to be exclusively a childhood disease. However, this highly contagious disease has resulted in healthcare-associated transmission in both patients and personnel. Seventeen healthcare providers were infected with pertussis from one infected infant. In another case, one healthcare provider was related to 87 cases. Immunity to pertussis is essential for HCP. The ACIP now recommends that those who provide direct patient care should receive a dose of tetanus, diphtheria, and pertussis (Tdap) vaccine.[19]

Postexposure prophylaxis is indicated for personnel exposed to pertussis. The regimen used is a 14-day course of either erythromycin 500 mg four times daily or one tablet of trimethoprim-sulfamethoxazole twice daily.[1]

Exposed personnel do not need to be excluded from duty. Personnel in whom symptoms develop (e.g., cough lasting 7 days or more, particularly if accompanied by paroxysms of coughing, inspiratory whoop, or post-tussive vomiting) should be excluded until 5 days after the start of appropriate therapy.

Influenza

Influenza is a contagious viral respiratory illness. The CDC reports that every year an average of 5 to 20 percent of the population in the United States gets seasonal influenza, resulting in more than 200,000 hospitalizations and about 3,000 to 49,000 deaths annually in the United States. Influenza causes mild to severe disease. Those at high risk for complications from influenza are seniors, infants and young children, persons with chronic medical conditions, and pregnant women.[20]

Symptoms of influenza include fever (usually high), headache, extreme tiredness, dry cough, sore throat, runny or stuffy nose, and muscle aches. Stomach symptoms, such as nausea, vomiting, and diarrhea, also can occur but are more common in children than adults. Complications of influenza include bacterial pneumonia, ear infections, sinus infections, dehydration, and worsening of chronic medical conditions, such as congestive heart failure, asthma, or diabetes.

Influenza viruses may be shed 1 day before the onset of symptoms and up to 5 days after the individual becomes ill. Spread of influenza mainly occurs when those with the illness cough or sneeze. Fomites contaminated with influenza viruses may also serve as a reservoir when individuals touch them and then touch their nose or mouth.

Each year influenza vaccination is recommended for HCP. The CDC[15] as well as a number of professional organizations, including APIC and the Society for Healthcare Epidemiology of America (SHEA),[21] have endorsed vaccination against influenza for all HCP. Many professional organizations, including SHEA, view influenza vaccination of HCP as a core patient safety practice and one in which

noncompliance should not be tolerated.[21]One goal for HCP immunization should be to administer the influenza vaccine to as many HCP as possible and preferably before influenza activity begins in the community. Therefore, an effective OHP in a healthcare organization must include an annual influenza prevention campaign that includes vaccination of HCP, especially those who provide direct care, as its primary focus. Education efforts that dispel the myths regarding influenza vaccine and relay the many benefits of receiving the vaccine yearly for individual HCP and HCP's coworkers and family members are other components that support this primary endeavor. Accrediting and regulatory agencies are increasingly adding components of a prevention and control program to their standards and requirements.

One example of a program is a modified mandatory program. HCP must receive the vaccine or sign a declination after reading the benefits of receiving vaccine versus risks to self and patients and others by not receiving the vaccine. In some healthcare facilities, if HCP refuses the influenza vaccine, it is mandatory that that HCP wear a barrier mask during influenza season when providing direct patient care. Another method that has been used successfully in increasing vaccination rates is providing a monetary incentive to receive the vaccine. Providing the vaccine at convenient times and locations has also increased compliance. There is a high compliance rate associated with mandatory programs that require receiving the vaccine as a condition of employment.

There are two types of the influenza vaccination. The former abbreviation TIV (trivalent inactivated influenza vaccine, previously used for inactivated influenza vaccines) has been replaced with the new abbreviation IIV (inactivated influenza vaccine). One is an inactive vaccine injection that is approved for use in people 6 months of age and older, including healthy people and people with chronic medical conditions. The nasal-spray flu vaccine is a vaccine made with live, weakened influenza viruses that do not cause influenza (live attenuated influenza vaccine [LAIV]). LAIV is approved for use in healthy people 2 to 49 years of age who are not pregnant.[19]An inactivated trivalent vaccine (TIV) containing 60 mcg of hemagglutinin antigen per influenza vaccine virus strain is an alternative inactivated vaccine for persons ≥65 years. The majority of TIV preparations are administered intramuscularly. An intradermally administered TIV was licensed in May 2011 and is an alternative for persons 18 to 64 years. RIV refers to recombinant hemagglutinin influenza vaccine and is egg-free and may be used for persons aged 18 to 49 years who have no other contraindications.

Initially there was concern that LAIV transmission from a recently vaccinated person could cause a clinically important illness in an immunocompromised contact. However, this has not been reported. There is a theoretical risk that a live, attenuated vaccine virus could be transmitted to the severely immune-suppressed person. Therefore, there is rationale for avoiding use of LAIV among HCP or other close contacts of severely immunocompromised persons. As a precautionary measure, HCP who receive LAIV should not provide care for severely immune-suppressed patients in protective environments for 7 days after vaccination. Hospital visitors who have received LAIV should also avoid contact with these designated patients. Some healthcare facilities expand this group, but this is outside of the CDC guidelines.

It takes about 2 weeks after vaccination for antibodies to develop that protect against influenza virus infection. Vaccines can be offered as early as September and continue throughout the influenza season often as late as March in the following year.

Another component of an influenza prevention and control program is providing chemoprophylaxis to patients, residents, and HCP when warranted, such as during an outbreak. Additional outbreak control measures include initiating Droplet Precautions and establishing cohorts of patients with confirmed or

suspected influenza. The unvaccinated staff should be re-offered influenza vaccinations. LAIV should be avoided because the antiviral medication will prevent viral replication needed to stimulate a vaccine response. Contact between ill staff or visitors and patients should be restricted. Adamantanes and neuraminidase inhibitors have been successfully used to control outbreaks caused by antiviral susceptible strains when antivirals are combined with other infection prevention measures. The CDC conducts enhanced surveillance in collaboration with local and state health departments. IPs should monitor information available on the incidence and resistance patterns identified in their communities. If an outbreak is caused by a strain of influenza virus that is not well matched by the vaccine for that season, chemoprophylaxis should be considered for all employees, regardless of their vaccination status.[20]

Infectious Processes with No Postexposure Interventions Indicated

There are common infectious processes for which there are no indications for postexposure intervention.

Herpes Simplex Virus

Personnel with primary or recurrent orofacial herpes simplex infections should be evaluated on a case-by-case basis to assess the potential for transmission to high-risk patients. High-risk patients include neonates, intensive care unit patients, patients with severe burns or eczema, and severely immunocompromised patients. Personnel with orofacial herpes simplex should be instructed to cover and not touch infected lesions. Observing hand hygiene policies is mandatory. Precautions need to be taken to prevent secretions from the lesions from having contact with patients with dermatitis. Herpetic whitlow is a herpes simplex infection of the fingers or hands. Personnel with herpetic whitlow need to be excluded from contact with patients until their lesions heal.[1]

Herpes Zoster Virus (Shingles)

Reactivation of latent varicella-zoster virus can occur decades after the initial infection known as chickenpox. This reactivation is known as zoster or shingles. It is a localized, generally painful cutaneous eruption that occurs most frequently among older adults and immunocompromised persons.

Transmission has been documented in healthcare settings between patients or from patients to HCP. However, transmission from HCP to patients has not been documented. Persons with localized zoster are less likely to transmit the virus to susceptible persons in household or occupational settings if their lesions are covered. Zoster lesions contain high concentrations of the zoster virus that can be spread, presumably by the airborne route, and cause primary varicella in exposed susceptible persons. Therefore, susceptible personnel should not provide direct patient care when other immune HCP are available. HCP can know when they are immune when their VZV antibodies are reactive. Localized zoster is only contagious after the rash erupts and until the lesions crust. Zoster is less contagious than varicella.[22]

Healthcare organizations may consider excluding personnel with zoster from work until their lesions dry and form a crust. Those with localized zoster should avoid contact with susceptible persons at high risk for severe varicella in household and occupational settings until lesions are crusted. Persons at high risk include pregnant women, all premature infants born to susceptible mothers, infants born at less than 28 weeks' gestation or who weigh 1,000 grams or less regardless of maternal immune status, and immunocompromised persons of all ages.[22]

In May 2006, the U.S. Food and Drug Administration (FDA) licensed a live attenuated vaccine for the prevention of herpes zoster and its sequelae. In June 2008, the ACIP released its recommendation for routine vaccination of all persons aged 60 years or older with one dose of zoster vaccine.

Cytomegalovirus

The two principle reservoirs of cytomegalovirus in healthcare facilities are infants and young children and immunocompromised patients. The consistent use of Standard Precautions when caring for all persons should interrupt spread from the person shedding the virus to personnel. There is no need to reassign pregnant HCP from caring for these patients. Pregnant personnel need to be counseled on how transmission occurs and the importance of infection prevention procedures to prevent transmission.[1]

Parvovirus

Human parvovirus B19 (B19) is the cause of erythema infectiosum (Fifth disease). This is a common rash illness, usually acquired in childhood. Although rare, transmission to HCP has been reported. B19 may be transmitted through contact with infected persons, fomites, or large droplets. Infected individuals are infectious before the appearance of the rash; those with infection and aplastic crisis for up to 7 days after onset of illness; and persons with chronic infection for years. Personnel should be educated about risks and infection prevention procedures. Pregnant personnel are at no greater risk for infection. However, if acquired during the first half of pregnancy, the risk for fetal death is increased. Therefore, girls and women of childbearing age should be instructed in risk for transmission and infection prevention procedures.[1]

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) can be transmitted directly through large droplets during close contact with infected individuals. Although RSV is most common in infants and children, outbreaks have been reported in bone marrow transplant units, intensive care units, and long-term care facilities. Transmission is greatest during the early winter months. RSV can occur simultaneously with other respiratory viruses and may go unrecognized. It may not be possible to restrict personnel with viral respiratory illness during the winter. Personnel with acute respiratory infections should be excluded from caring for high-risk patients.[1]

Staphylococcal Infection or Carriage

Personnel with a draining lesion suspected to be caused by *Staphylococcus aureus(S.aureaus)*need to be excluded from patient care or food handling until appropriate culture results have ruled out infection or adequate therapy has resulted in resolution of their infection. Only those workers who are epidemiologically linked to disseminating the organism should be cultured. Culture surveys of personnel can detect carriers, but do not indicate when carriers are likely to disseminate organisms.[1]

Multidrug-resistant Organisms and Healthcare Personnel

There are no recommendations for restrictions of HCP who are colonized with multidrug-resistant organisms, such as methicillin-resistant *S. aureus*(MRSA), unless a person is epidemiologically linked to transmission within the facility. As with any active infection, HCP who have draining skin lesions should be removed from patient care activities or food handling until the person receives appropriate therapy and the infection has resolved.

Pregnant Healthcare Personnel

Pregnant HCP often express concern that they may be at increased risk for acquisition of infections because of their pregnancy. There are few instances when work restrictions are recommended for the pregnant HCP. See **104. Pregnant Healthcare Personnel**.

Emerging Pathogens

Vaccinia (Smallpox)

In 1980, smallpox was eradicated as a naturally occurring disease. It is feared that this disease may be brought back as a biological weapon. Supplemental recommendations from the ACIP published in 2003 asked communities and acute care hospitals to form smallpox preparedness teams who would be vaccinated and ready to care for infected patients if there was a smallpox attack. State and local health departments have since requested that the CDC provide guidance regarding appropriate interval for revaccination of individuals who participate in the civilian smallpox responder vaccination program. The CDC has released the following recommendation.

After consideration of available scientific evidence and the practical issues relevant to pre-event vaccination, CDC recommends revaccination of volunteer responders from the pre-event smallpox program on an as-needed, "out-the-door" basis. "Out-the-door" basis is defined as receiving revaccination only after there is determination of a credible smallpox threat to public health and prior to engaging in activities involving a risk of exposure to smallpox virus. "Out-the-door" revaccination would only apply to first responders who had been vaccinated as part of the U.S. Civilian Smallpox Preparedness and Response and had a documented vaccine "take." A "take" typically appears as a vesicle surrounded by a red areola, which becomes umbilicated and then pustular by days 7 to 11 after vaccination. Skin reactions after revaccination are typically less pronounced with more rapid progression and healing than those after primary vaccinations. The "out-the-door" recommendation would be activated only after a smallpox outbreak is confirmed or highly suspected, or there is credible evidence of a release or imminent release of smallpox virus.[23]

The vaccinia virus is similar to smallpox virus, but is less harmful and will protect against smallpox. There is a usual progression of the vaccination site and special precautions that need to be followed so as not to self-inoculate or spread to close household contacts or persons to whom they provide care.[24]

The CDC has begun distribution of a new-generation smallpox vaccine, to civilian laboratory personnel, the military, and state public health preparedness programs. This is a live, vaccinia virus smallpox vaccine derived from plague purification cloning. The FDA licensed this vaccine for use in the United States in August 2007.

Severe Acute Respiratory Syndrome

There are viruses that cause respiratory infections that are well known whereas others are newly discovered, such as human metapneumovirus and Middle East respiratory syndrome coronavirus (MERS-CoV). HCP need to recognize the importance of consistently applying Standard Precautions when caring for all patients. Severe acute respiratory syndrome (SARS) serves as an example of how an emergent virus can be present in a population and go undetected as an emerging pathogen exposing unsuspecting HCP.

SARS has been transmitted within a healthcare facility, and most often the source of transmission has been an unidentified case or failure to don and remove PPE appropriately. Occupational acquisition of

SARS has been documented. Therefore, the OHP in a healthcare facility that could possibly care for a patient with SARS has to include elements that address personnel issues associated with SARS.[25]

HCP should be informed that they are expected to comply with all infection prevention and public health recommendations. They should also be made aware that those recommendations may change as a SARS outbreak progresses.

An exposure reporting process needs to be established. This process should include methods for identifying exposed personnel (e.g., self-reporting by employees and logs of personnel entering the rooms of patients with SARS). Measures should be developed for symptom monitoring in accordance with public health recommendations. Systems need to be developed for HCP follow-up and possible work restrictions after unprotected exposures to patients with SARS. Personnel need to be instructed to notify each facility at which they work if any one of those facilities is providing care to SARS patients. Quarantine may be used as an exposure management tool, and appropriate measures need to be developed to help personnel comply with restriction.

HCP will need to have access to mental health professionals to help them cope with the emotional strain of managing a SARS outbreak.

Avian Influenza

Avian influenza is commonly called bird flu. Infections with avian influenza viruses in domestic poultry cause two main forms of disease. They are distinguished by low and high extremes of virulence. The low pathogenic form may go undetected and usually causes only mild symptoms. The highly pathogenic form spreads more rapidly through flocks of poultry, may cause disease that affects multiple internal organs, and has a mortality rate of 90 to 100 percent, often within 48 hours. Type A influenza viruses have many different subtypes. The subtypes differ because of changes in certain proteins on the surface of the influenza A virus (hemagglutinin [HA] and neuraminidase [NA] proteins). There are 16 known HA subtypes and nine known NA subtypes of influenza A viruses and many different combinations of HA and NA proteins are possible. Each combination represents a different subtype. All known subtypes of influenza A viruses can be found in birds. Infections with these avian influenza viruses can occur in humans. Most of the infections occurring in humans are the result of contact with infected poultry or surfaces contaminated with the secretions and/or the excretions from infected birds. Spread from one ill person to another has been reported rarely, and these reports have been limited and unsustained. It is likely that the three known A subtypes of the human influenza viruses that currently circulate among humans originally came from birds. These are H1N1, H1N2, and H3N2. The influenza A viruses are constantly changing. They may adapt over time to infect and spread among humans.[26]

Avian influenza in humans may present with typical human influenza symptoms such as fever, cough, sore throat, and muscle aches. The infection can also present as eye infections, pneumonia, severe respiratory diseases (e.g., acute respiratory distress), and other severe and life-threatening complications. The symptoms may depend on which virus caused the infection. Prescription medicines approved in the United States for human influenza viruses should work in treating avian influenza infection in humans. However, resistance to these drugs may develop, so these medications may not always be effective. Additional studies are needed to demonstrate the effectiveness of these medicines.

The avian influenza virus H5N1 has caused the largest number of detected cases of severe disease and death in humans. More than half of the people reported infected with the virus have died. However, H5N1 remains a very rare disease in humans. The virus does not infect humans easily, and person-to-

person spread is difficult. Most severely ill people are more likely to be diagnosed and reported, and milder cases may go unreported. For current information about avian influenza and cumulative case numbers, see the World Health Organization (WHO) avian influenza website.

WORKERS' COMPENSATION

The IP may be asked to help assess a situation to determine if a worker has experienced occupational acquisition of an infectious agent or disease. The IP should be familiar with the workers' compensation system in place within their facility.

The workers' compensation system is a wage-replacement system of disability insurance for the individual who sustains an illness or injury in the course of employment. Most expenses related to the illness or injury, including medical and other costs associated with the rehabilitation, is covered. These programs vary from state to state and country to country. The laws are designed to relieve employers of liability from common-law suits involving negligence and are based on employer-employee relationship instead of theory of negligence. The laws hold that the employers insure costs of occupational disabilities without regard to any fault involved. Most jurisdictions require employers to obtain insurance or prove financial ability to carry their own risk (e.g., self-insured). In some states the employees may choose between accepting compensation provided by law or instituting a lawsuit against the employer.[27,28,29,30,31]

The components of a workers' compensation program may include medical benefits, weekly compensation benefits, safety and rehabilitation programs charged to study the cause of accidents and promote prevention, and retraining of workers who are unable to return to their pre-injury status.

All states in the United States recognize responsibility for specific provisions for occupational diseases. Disease that results from occupational exposure usually is eligible for compensation if the occupational exposure is the sole cause of disease; the occupational exposure is one of several causes of the disease; the occupational exposure aggravates a pre-existing disease (e.g., asthma); or the occupational exposure hastens the onset of disability. The burden of proving that disease was occupationally acquired lies with the workers. Most states do not provide compensation for a disease that is an ordinary disease of life (e.g., stroke, heart attack).

MEASURING IMPROVEMENT IN PREVENTING OCCUPATIONAL EXPOSURE

When applied to occupational health and safety, surveillance involves collection, analysis, and dissemination of data on hazards that have endangered or may endanger HCP. The current emphasis is on protecting HCP from occupational acquisition of disease. There is a need to evaluate interventions and practices for effectiveness.

An epidemiological approach can be taken to manage occupational exposures.[21] Reductions or increases in injuries and exposures are monitored over time. The causes of the injuries and exposures are then identified. Variations that occur are analyzed. Prevention strategies are designed and implemented. The effectiveness of prevention strategies is tracked by comparing injury and exposure rates to previous rates. Feedback is then provided to the HCP involved in the effectiveness of the prevention strategies.

The rates of reported injuries and exposures for measuring performance improvement are calculated in the following ways:[32]

1. The average daily census of occupied beds in the institution for the same year can be used as the denominator that can be compared with other institutions. For example,
   - Total number of needlesticks reported in 1 year divided by
   - Total number of occupied beds/average daily census
   - Equals the number of needlesticks per bed per year
2. The rates can be identified per occupational category. For example,
   - Total number of needlesticks reported by nurses in 1 year divided by
   - Number of full-time equivalent nurses employed in that year
   - Equals the rate of needlesticks per full-time equivalent nurse per year
3. A device-based rate can be used to compare needlestick risk from different devices and to evaluate the effectiveness of the product design. The type of needle must be identified when each needlestick is reported. For example:
   - Number of needlesticks from device type in 1 year divided by
   - Number of that device type used or purchased in same year
   - Equals the number of needlesticks per device type in 1 year

Conclusions

The role of the IP in an OHP in a healthcare facility is to provide reassurance to personnel concerned with issues relating to infectious agents that may be encountered in the workplace. The IP may also participate in designing plans that address emerging pathogens and possible bioterrorism agents. The IP's knowledge of the principles of how infectious agents are spread and proven control measures can be invaluable when an organization is faced with the need to address an emergent situation.

As a review of the information provided in this chapter, the reader should review the two scenarios that follow and ensure understanding of actions taken.

SCENARIO 1: MENINGOCOCCAL EXPOSURE

A 17-year-old female Caucasian patient presented to the emergency department on a Saturday afternoon with fever, headache, nausea and vomiting, stiff neck, and a petechial rash. A spinal tap was performed, and the spinal fluid Gram stain demonstrated Gram-negative diplococci. At the time of the patient's admission, bacterial antigen panels were still performed and the one performed on her spinal fluid was positive for *Neisseria meningitidis*.

The IP noted the laboratory results on Monday morning and called the employee health department to see if the staff were aware of the situation. The employee health nurse replied that she had been receiving calls from emergency department staff that were on duty on Saturday evening. The IP and employee health nurse referred to the organization's protocol approved by the medical director to determine who should receive postexposure prophylaxis (PEP). Staff members who did not have a procedure mask in place and actually examined the oropharynx, intubated or assisted with intubation, or gave mouth-to-mouth resuscitation (for which there was no need in this case) would be offered PEP. Because the appropriate precautions recommended for meningococcal disease are Droplet Precautions, they determined that they may offer PEP to those staff members who were unprotected and assisted in the spinal tap or were within 3 feet of the patient's oropharynx.

The staff members who provided care to this patient were screened to determine potential exposure. If they met the established criteria to receive PEP, they were offered a one-time dose of ciprofloxacin 500 mg by mouth. If there was a pregnant staff member, she would have been offered a one-time dose of ceftriaxone 250 mg intramuscularly. Azithromycin in a single dose has also been effective.

Five staff members received PEP. The emergency department staff admitted they did not wear a procedure mask during the initial assessment of the patient or when performing the spinal tap. There were no secondary cases identified. Ideally, antimicrobial chemoprophylaxis should be administered less than 24 hours after identification of the index patient. Chemoprophylaxis administered more than 14 days after onset of illness in the index patient is probably of limited or no value.[33]

SCENARIO 2: DISSEMINATED HERPES ZOSTER AND SUSCEPTIBLE HEALTHCARE PERSONNEL

A 24-year-old female RN who works in a community acute care hospital provided a history of never having chickenpox during her post-hire assessment. This history was confirmed when the results of her varicella zoster antibody indicated she was susceptible. She received two doses of the varicella vaccine and was instructed to report any exposures to varicella in the community or in the hospital. One evening she admitted a patient to the medical unit who had a generalized rash. The following day the physician diagnosed the patient's vesicular rash as disseminated shingles (herpes zoster), and the patient was placed in Airborne Isolation as well as Contact Precautions.

The RN reported her unprotected exposure to the employee health service. She was monitored daily during days 10 to 21 after her exposure. The process was for her to report to employee health service each day she was on duty during this time period to determine whether any of the following symptoms were present: fever, skin lesions, or systemic symptoms. On the days that she was not on duty she was to call the employee health service if any symptoms occurred. She did not exhibit any evidence of acquiring varicella from this exposure.

If this RN had been pregnant, she would have been referred to her obstetrician to consider whether she should receive VZIG because of the exposure. If she had received VZIG, her monitoring would have been extended from 21 to 28 days after her exposure because VZIG may delay the onset of disease.

Future Trends

The potential of emerging pathogens yet to be identified is real. The IP plays a vital role in ongoing education of the worker population and as an advisor to administration when planning for an event. HCP need to recognize the importance of hand hygiene practices, Standard Precautions, respiratory hygiene, and Transmission-based Precautions to reduce the risk for transmission within the healthcare facility and into the community.

International Perspective

The SARS outbreak of 2003 began in one country and spread to other continents by way of international travel. This epidemic demonstrated the need for all countries to be vigilant about the incidence of infectious diseases worldwide. In April 2012 another viral respiratory illness caused by a coronavirus was first reported in Saudi Arabia and has been linked to four countries on the Arabian Peninsula. Referred to as MERS-CoV, concern worldwide exists regarding the potential for spread to

additional countries.[34]The literature has reported the spread of vaccine-preventable diseases introduced into a previously vaccinated but waning population from individuals who traveled from areas where vaccinations were not as prevalent or readily available.

When planning an OHP for a healthcare facility, consideration needs to be made for the incidence of infectious diseases identified in the community that may be introduced into the HCP pool. The infectious diseases may differ from country to country and from areas within a country.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Occupational Exposure to Bloodborne Pathogens

Author(s): Sonia Miller, RN, BSN, MSN, CIC
Chief, Infection Prevention & Control

Fort Belvoir Community Hospital
Fort Belvoir, VA

Published: October 3, 2014

Abstract

Preventing transmission of bloodborne viruses in healthcare settings requires a multifaceted approach, including promoting Hepatitis B vaccination of all healthcare personnel who may have contact with blood or body fluids, considering all patients as potentially infectious, using appropriate barriers to prevent blood and body fluid contact, preventing percutaneous injuries by eliminating unnecessary needle use, implementing devices with safety features, using safe work practices when handling needles and other sharp devices, and safely disposing of sharps and blood-contaminated materials. Postexposure management is also an integral component of a complete program to prevent infection following bloodborne pathogen exposure and an important element of workplace safety. This chapter focuses on the risk and management of occupational blood exposures.

Key Concepts

- Prevention of occupational blood exposures is the primary way to reduce transmission of Hepatitis B virus, Hepatitis C virus, and human immunodeficiency virus among healthcare personnel.
- Healthcare personnel who may come into contact with blood and body fluids should be vaccinated against Hepatitis B.
- The risk of Hepatitis B virus seroconversion after a percutaneous injury ranges from 23 to 62 percent depending on the Hepatitis B e antigen status of the source person.
- The average risk of seroconversion after a percutaneous injury involving blood infected with Hepatitis C virus is approximately 1.8 percent.
- The average risk of seroconversion after a percutaneous injury involving blood infected with human immunodeficiency virus is approximately 0.3 percent.

- All healthcare personnel taking human immunodeficiency virus postexposure prophylaxis should be evaluated within 48 to 72 hours after exposure and monitored for drug toxicity for at least 2 weeks.
- Healthcare organizations and facilities should set up programs to prevent exposure to bloodborne viruses and to manage cases of exposure if they occur.

Background

Exposure to bloodborne pathogens poses a serious risk to healthcare personnel (HCP). Avoiding occupational blood exposures through adherence to Standard Precautions and other safe work practices is essential. The most effective means to prevent transmission of Hepatitis B virus (HBV), Hepatitis C virus (HCV), and human immunodeficiency virus (HIV) in healthcare settings include Hepatitis B vaccination, the use of appropriate barriers to prevent blood and body fluid contact, and preventing percutaneous injuries by eliminating unnecessary needle use, implementing devices with safety features, using safe work practices when handling needles and other sharp devices, and safely disposing of sharps and blood-contaminated materials. Despite improved methods of preventing exposure, occupational exposures continue to occur. In this chapter, we provide information about HBV, HCV, and HIV infection and review the risk and management of occupational blood exposure, including recommendations for postexposure prophylaxis (PEP).

Basic Principles

DEFINITION OF HEALTHCARE PERSONNEL AND EXPOSURE

In this context, healthcare personnel (HCP) is defined as all persons (e.g., employees, students, contractors, attending clinicians, public safety workers, or volunteers) whose activities involve contact with patients or with blood or other body fluids from patients in a healthcare, laboratory, or public safety setting.[1,2]

An exposure that might place HCP at risk for HBV, HCV, or HIV infection is defined as a percutaneous injury (e.g., a needlestick or cut with a sharp object) or contact of mucous membrane or nonintact skin (e.g., exposed skin that is chapped, abraded, or afflicted with dermatitis) with blood, tissue, or other body fluids that are potentially infectious.[1,2,3]The probability of infection after exposure of a susceptible person depends on the route of exposure, the concentration of infectious virions in the implicated body fluid, the volume of infective material transferred, and, for HBV, the susceptibility of the exposed person.

In addition to blood and body fluids containing visible blood, semen and vaginal secretions are also considered potentially infectious. Although semen and vaginal secretions have been implicated in the sexual transmission of HBV, HCV, and HIV, they have not been implicated in occupational transmission from patients to HCP. The following fluids also are considered potentially infectious: cerebrospinal fluid, synovial fluid, pleural fluid, peritoneal fluid, pericardial fluid, and amniotic fluid. The risk for transmission of HBV, HCV, and HIV infection from these fluids is unknown; the potential risk to the HCP from occupational exposures to these fluids has not been assessed by epidemiologic studies in healthcare settings. Feces, nasal secretions, saliva, sputum, sweat, tears, urine, and vomitus are not considered potentially infectious unless they contain blood. The risk for transmission of HBV, HCV, and HIV infection from these fluids and materials is extremely low.

Any direct contact (i.e., contact without barrier protection) to concentrated virus in a research laboratory or production facility is considered an exposure that requires clinical evaluation. For human bites, the clinical evaluation must include the possibility that both the person bitten and the person who inflicted the bite were exposed to bloodborne pathogens. Transmission of HBV or HIV infection by this route has rarely been reported.[4,5,6]

Bloodborne Pathogens And Occupational Exposure

HEPATITIS B VIRUS

Epidemiology

HBV is transmitted by percutaneous or mucosal exposure to infectious blood or body fluids. HBV is comparatively stable in the environment; it is resistant to drying, simple detergents, and alcohol; and it has been found to remain viable at room temperatures for 7 days or longer.[7,8]Infectious levels of HBV DNA can be detected on environmental surfaces in the absence of visible blood.[7]

For adults, the two primary sources of HBV infection are sexual contact and percutaneous exposure to blood.[7]Among susceptible HCP, in the absence of PEP, the risk of HBV infection after a needlestick injury is 37 to 62 percent if the source patient is Hepatitis B e antigen (HBeAg) positive and 23 to 37 percent if the patient is HBeAg negative.[2]Because infected patients can have high concentrations of HBV in blood or body fluids and HBV is stable at ambient temperatures, transmission of HBV also can occur in healthcare settings through less apparent modes, such as exposure to contaminated environmental surfaces or equipment that has been inadequately disinfected or through exposures of nonintact skin. Many of the infections that occurred before widespread vaccination of HCP likely resulted from such exposures (e.g., inoculation into cutaneous scratches, lesions, or mucosal surfaces).[2,8,9]The estimated number of HBV infections among HCP in the United States has decreased from more than 10,000 in 1983 to fewer than 400 in 2002.[8]

Clinical Features

HBV infection can produce either asymptomatic or symptomatic infection. The average incubation period is 90 days (range: 60 to 150 days) from exposure to onset of jaundice and 60 days (range: 40 to 90 days) from exposure to onset of abnormal serum alanine aminotransferase (ALT) levels. HBV infection results in clinically apparent hepatitis in about one-third of acutely infected adults. Jaundice, dark urine, and scleral icterus usually are present by the time patients seek medical attention. The most striking laboratory findings are extreme elevations in the serum aminotransferase levels. ALT and aspartate aminotransferase (AST) levels may be elevated to more than 10 times the normal levels, whereas the alkaline phosphatase levels are increased to a much lesser extent. The fatality rate among persons with reported cases of acute Hepatitis B is 0.5 to 1.0 percent, with the highest rates in adults older than 60 years.[7]Among adults with acute HBV infection, less than 5 percent progress to chronic HBV infection and are at risk for chronic hepatitis, cirrhosis, and primary hepatocellular carcinoma.

Laboratory Diagnosis

Hepatitis B is differentiated from other causes of hepatitis by serologic assays (Table 101-1).[7,9] Several well-defined antigen-antibody systems are associated with HBV infection, including Hepatitis B surface antigen (HBsAg) and antibody to Hepatitis B surface antigen (anti-HBs); Hepatitis B core antigen (HBcAg) and anti-HBc; and HBeAg and antibody to HBeAg (anti-HBe). Serologic assays are commercially available for all of these except HBcAg because no free HBcAg circulates in blood. These markers of HBV infection change over time, with different patterns seen in patients with acute infection that resolves and patients with chronic infection (Table 101-1).

Table 101-1 Interpretation of Patterns of Hepatitis B Virus Serologic Markers

Serologic Markers				
HBsAg	Total Anti-HBc	IgM Anti-HBc	Anti-HBs	Interpretation
—	—	—	—	Susceptible, never infected
+	—	—	—	Acute infection, early incubation**
+	+	+	—	Acute resolving infection
+	—	—	—	Acute resolving infection
—	+	—	+	Past infection, recovered and immune
+	+	—	—	Chronic infection
—	+	—	—	False positive (i.e., susceptible), past infection, or "low-level" chronic infection
—	—	—	+	Immune if titer is ≥10 mIU/mL

Abbreviations: HBsAg, Hepatitis B surface antigen; Anti-HBc, antibody to Hepatitis B core antigen. The total anti-HBc assay detects both IgM and IgG antibody; IgM, immunoglobulin M; Anti-HBs, antibody to Hepatitis B surface antigen; +, positive; —, negative.
**Transient HBsAg positivity (lasting 18 days or less) might be detected in some patients during vaccination.
Adapted from Table 1, Recommendations for preventing transmission of infections among chronic hemodialysis patients. *MMWR Recomm Rep*2001 Apr 26;50(No. RR-05):1–43.

Transient HBsAg positivity has been reported for as long as 18 days after Hepatitis B vaccination and is clinically insignificant.[7] Otherwise, the presence of HBsAg is indicative of ongoing HBV infection and potential infectiousness. In newly infected persons, HBsAg is present in serum 6 to 60 days (mean, 30

days) after exposure to HBV and persists for variable periods. Anti-HBc develops in all HBV infections, appearing at onset of symptoms or liver test abnormalities in acute HBV infection, rising rapidly to high levels, and persisting for life. Acute or recently acquired infection can be distinguished by the presence of the immunoglobulin M (IgM) class of anti-HBc, which persists for approximately 6 months.

In persons who recover from HBV infection, HBsAg is eliminated from the blood and anti-HBs develop, typically within 3 to 4 months. The presence of anti-HBs indicates immunity from HBV infection. After recovery from natural infection, most persons will be positive for both anti-HBs and anti-HBc, whereas only anti-HBs develop in persons who are successfully vaccinated against Hepatitis B. The persistence of HBsAg for 6 months after the diagnosis of acute HBV is indicative of progression to chronic HBV infection. Persons who do not recover from HBV infection and become chronically infected remain positive for HBsAg (and anti-HBc), though a small proportion (0.5 to 2 percent per year) clear HBsAg and develop anti-HBs.[7]

HBeAg can be detected in the serum of persons with acute or chronic HBV infection. The presence of HBeAg correlates with viral replication and high levels of virus (i.e., high infectivity). Anti-HBe correlates with the loss of replicating virus and with lower levels of virus. However, all HBsAg-positive persons should be considered potentially infectious, regardless of their HBeAg or anti-HBe status. HBV infection can also be detected using qualitative or quantitative tests for HBV DNA. These tests are most commonly used for patients being managed with antiviral therapy.

Treatment, Prevention, and Control

No specific treatment exists for acute Hepatitis B; supportive care is the mainstay of therapy. Persons who have chronic HBV infection require medical evaluation and regular monitoring. The initial evaluation of patients with chronic HBV infection includes history, physical examination, and laboratory testing to assess the following: liver disease, HBV replication (e.g., HBeAg, anti-HBe, and HBV DNA), and viral coinfections.[10]Therapeutic agents approved by the U.S. Food and Drug Administration (FDA) for treatment of chronic Hepatitis B can achieve sustained suppression of HBV replication and remission of liver disease in certain persons. At present, seven drugs are licensed in the United States for the treatment of HBV infection: interferon alfa, pegylated interferon alfa-2a, lamivudine, adefovir, entecavir, telbivudine, and tenofovir.[10,11]Persons with chronic HBV infection can benefit from counseling regarding ways to prevent transmitting HBV infection to others.[7,12,13]Vaccination of sexual and household contacts is recommended to prevent transmission.[7,12]

Hepatitis B vaccination is the most effective measure to prevent HBV infection and its consequences.[7]

Hepatitis B vaccine provides both pre- and postexposure protection against HBV infection. The currently available vaccines in the United States are produced by recombinant DNA technology. Three intramuscular doses of Hepatitis B vaccine induce a protective antibody response in more than 90 percent of healthy recipients. Adults who develop a protective antibody response are protected from clinical disease and chronic infection. The duration of vaccine protection is under investigation, but available evidence indicates that nearly all vaccinated persons remain protected against HBV infection.[7]

HCP at ongoing risk for percutaneous injuries should be tested 1 to 2 months after completion of the three-dose vaccination series for anti-HBs.[2]Factors associated with a lack of response include improper vaccination (e.g., improperly stored vaccine, gluteal inoculation, subcutaneous injection, improperly timed dosing), obesity, older age, and smoking. Persons who do not experience response to the primary vaccine series should receive a second three-dose series or be evaluated for HBsAg positivity. Booster

doses of Hepatitis B vaccine are not necessary, and periodic serologic testing to monitor antibody concentrations after completion of the vaccine series is not recommended.

Since 1982, substantial progress has been made toward reducing the risk for HBV infection in adults.[7,14]

The Occupational Safety and Health Administration's (OSHA's) Bloodborne Pathogen Standard mandates provision of Hepatitis B vaccine at no cost to all HCP and others at occupational risk for blood exposure.[15]The substantial declines in the incidence of acute Hepatitis B that have occurred among HCP have been attributed to implementation of Standard Precautions in healthcare settings, use of sharps with safety features, increasing levels of Hepatitis B vaccination coverage among HCP, and use of PEP.[8]

Postexposure Prophylaxis

The need for prophylaxis for persons sustaining accidental percutaneous or mucosal exposures to blood should be based on several factors, including the HBsAg status of the source and the Hepatitis B vaccination and vaccine-response status of the exposed person. Such exposures usually involve persons for whom Hepatitis B vaccination is recommended. Any blood or body fluid exposure to unvaccinated HCP should lead to initiation of the Hepatitis B vaccine series. Table 101-2 summarizes recommendations for prophylaxis after percutaneous or mucosal exposure to blood according to the HBsAg status of the exposure source and the vaccination and vaccine-response status of the exposed person.[2]

When Hepatitis B immune globulin (HBIG) is indicated, it should be administered as soon as possible after exposure (preferably within 24 hours). The effectiveness of HBIG when administered later than 7 days after exposure is unknown. When Hepatitis B vaccine is indicated, it should also be administered as soon as possible (preferably within 24 hours) and can be administered simultaneously with HBIG at a separate site (vaccine should always be administered in the deltoid muscle).[2]

For exposed persons who are in the process of being vaccinated but have not completed the vaccination series, vaccination should be completed as scheduled, and HBIG should be added as indicated (Table 101-2). Persons exposed to HBsAg-positive blood or body fluids that are known not to have a response to a primary vaccine series should receive a single dose of HBIG and should reinitiate the Hepatitis B vaccine series with the first dose of the Hepatitis B vaccine as soon as possible after exposure. Alternatively, they should receive two doses of HBIG, one dose as soon as possible after exposure, and the second dose 1 month later. The option of administering one dose of HBIG and reinitiating the vaccine series is preferred for nonresponders who did not complete a second three-dose vaccine series. For persons who previously completed a second vaccine series but did not develop a response, two doses of HBIG are preferred.[2]

Table 101-2 Recommended Postexposure Prophylaxis for Exposure to Hepatitis B Virus

	Treatment		
Vaccination and Antibody Response Status of Exposed HCP*	Source HBsAg† Positive	Source HBsAg† Negative	Source Unknown or Not Available for Testing

Unvaccinated	HBIG§ × 1 and initiate Hepatitis B vaccine series	Initiate Hepatitis B vaccine series	Initiate Hepatitis B vaccine series
Previously vaccinated Known responder¶ Known nonresponder** Antibody response unknown	No treatment HBIG × 1 and initiate revaccination or HBIG × 2†† Test exposed person for anti-HBs§§ 1. If adequate,¶no treatment is necessary 2. If inadequate,** HBIG × 1 and vaccine booster	No treatment No treatment No treatment	No treatment If known high-risk source, treat as if source were HBsAg positive Test exposed person for anti-HBs: 1. If adequate, no treatment is necessary 2. If inadequate, administer vaccine booster and recheck titer in 1–2 months

*Persons who have previously been infected with HBV are immune to reinfection and do not require postexposure prophylaxis.
†Hepatitis B surface antigen.
§Hepatitis B immune globulin; dose is 0.06 mL/kg intramuscularly.
¶A responder is a person with adequate levels of serum antibody to HBsAg (i.e., anti-HBs ≥10 mIU/mL).
**A nonresponder is a person with inadequate response to vaccination (i.e., serum anti-HBs <10 mIU/mL).
††The option of giving one dose of HBIG and reinitiating the vaccine series is preferred for nonresponders who have not completed a second three-dose vaccine series. For persons who previously completed a second vaccine series but did not respond, two doses of HBIG are preferred.

HEPATITIS C VIRUS

Epidemiology

HCV infection is the most common chronic bloodborne infection in the United States, affecting an estimated 3.2 million persons.[16] HCV-associated end-stage liver disease is the most frequent indication for liver transplantation among U.S. adults.[17]

The incubation period for acute HCV infection ranges from 2 to 24 weeks (averaging 6 to 7 weeks).[17]

HCV transmission occurs primarily through exposure to infected blood. Injection drug use remains the most commonly identified risk factor for transmission, but other transmission modes include transfusion and solid organ transplantation from infected donors, unsafe medical practices, occupational exposure to infected blood, birth to an infected mother, and sex with an infected partner.

HCP exposed to infected blood through needlestick injuries may acquire HCV infection; the transmission risk per exposure is approximately 1.8 percent.[2]Injuries resulting in deep punctures or wounds with bleeding and procedures involving a needle placed in a patient's artery or vein increase the risk of HCV transmission.[18]Transmission rarely occurs from mucous membrane exposures to blood, and, more rarely, has been documented from nonintact skin exposures to blood.[19]

Data are limited on survival of HCV in the environment. Degradation of HCV occurs when serum containing HCV is left at room temperature. Specific animal infectivity studies have shown survival as long as 16 hours but not longer than 4 days.[20]The potential for environmental survival of HCV suggests that environmental contamination with blood containing HCV could pose a risk for transmission in the healthcare setting. The risk for transmission from exposure to fluids or tissues other than HCV-infected blood has not been quantified but is expected to be low. HCV is not known to be transmissible through the airborne route or through casual contact in the workplace.

Clinical Features

HCV infection produces a spectrum of clinical illness similar to that of HBV infection and is indistinguishable from other forms of viral hepatitis based on clinical symptoms alone. Serologic tests are necessary to establish a specific diagnosis of Hepatitis C. Most adults acutely infected with HCV are asymptomatic. After acute infection, 15 to 25 percent of persons appear to resolve their infection without sequelae, as defined by sustained absence of HCV RNA in serum and normalization of ALT levels.[17]

Chronic HCV infection develops in most people (75 to 85 percent); 60 to 70 percent of these chronically infected people have persistent or fluctuating ALT elevations, indicating active liver disease. Thus, a single ALT determination cannot be used to exclude ongoing hepatic injury, and long-term follow-up of patients with HCV infection is required to determine their clinical outcome or prognosis.

The course of chronic liver disease is usually insidious, progressing slowly without symptoms or physical signs in the majority of patients during the first two or more decades after infection.[17]Chronic Hepatitis C frequently is not recognized until asymptomatic persons are identified as HCV-positive during blood-donor screening or elevated ALT levels are detected during routine physical examinations. Most studies have reported that cirrhosis develops in 10 to 20 percent of persons with chronic Hepatitis C over a period of 20 to 30 years, and hepatocellular carcinoma in 1 to 5 percent, with striking geographic variations in rates of this disease. However, when cirrhosis is established, the rate of development of hepatocellular carcinoma might be as high as 1 to 4 percent per year.

Laboratory Diagnosis

Laboratory testing is necessary to establish a specific diagnosis of Hepatitis C.[9,17,21]The two major types of tests available for the laboratory diagnosis of HCV infections are serologic assays for antibodies to HCV (anti-HCV) and nucleic acid tests to detect HCV RNA. Testing for anti-HCV is recommended for initially identifying persons with HCV infection and includes initial screening with an immunoassay, and, if

positive, confirmation by an additional, more specific, assay.[21]Anti-HCV may be detected within 5 to 6 weeks after the onset of infection, but it is not possible to determine if someone has acute, chronic, or past infection with an anti-HCV test. HCV RNA may be detected within 1 to 2 weeks of exposure to the virus and several weeks before elevations of ALT and detection of anti-HCV.

Treatment, Prevention, and Control

HCV-positive persons benefit from evaluation for the presence and severity of chronic liver disease.[17] Antiviral therapy is recommended for persons with persistently elevated ALT levels, detectable HCV RNA, and a liver biopsy that indicates either portal or bridging fibrosis or moderate degrees of inflammation and necrosis. No clear consensus exists on whether to treat patients with persistently normal serum transaminases. Successful treatment eliminates viremia and the potential for HCV transmission and further chronic liver disease.[22,23]In randomized clinical trials, the highest response rates have been achieved with the combination of weekly subcutaneous injections of long-acting peginterferon alfa and oral ribavirin. This combination of drugs has resulted in virus elimination (sustained virologic response) in 40 to 50 percent of treated persons infected with genotypes 1 or 4 and in 75 to 85 percent of those infected with genotypes 2 or 3.[22,23]

No vaccine against HCV infection exists. National recommendations for prevention and control of HCV infection, issued in 1998, emphasize primary prevention activities to reduce the risk for HCV transmission.[17]These activities include screening and testing of blood donors, viral inactivation of plasma-derived products, risk-reduction counseling and screening of persons at risk for HCV infection, and adherence to Standard Precautions and safe work practices in healthcare settings.

Postexposure Management

PEP with immunoglobulin antiviral agents or immunomodulators is not recommended after exposure to HCV-positive blood.[2,24]There is currently no PEP for HCV; the intent of current U.S. recommendations for postexposure management is to achieve early identification of chronic infection and, if present, referral to a specialist knowledgeable in this area for additional follow-up and medical management.[2]

According to U.S. Public Health Service guidelines, HCP who have been exposed to an HCV-positive source should have baseline testing for anti-HCV and ALT activity performed, followed by testing for anti-HCV and ALT activity at 4 to 6 months after the exposure to detect infection. These guidelines also indicate that testing for HCV RNA may be performed 4 to 6 weeks after exposure if earlier detection of infection is desired.[2]

Early detection strategies, which call for more frequent and aggressive testing to monitor the exposed individual, have been advocated for several reasons.[24,25]First, this approach might help alleviate some of the worker's stress and anxiety associated with the exposure or reduce loss to follow-up.[25]Second, limited data indicate that antiviral therapy might be most effective when started early in the course of HCV infection.[2,22,24,25]Although the optimal timing for initiating treatment has not been determined, current practice guidelines support a delay of 2 to 4 months after acute onset to allow for spontaneous clearance.[22]This issue is further complicated by additional questions regarding optimal treatment regimens and duration of treatment.[22]The need for experienced providers to evaluate and discuss

treatment options underscores the importance of appropriate medical referrals and counseling as part of HCV postexposure management.[2,24]

HUMAN IMMUNODEFICIENCY VIRUS

Epidemiology

In the United States, approximately 1.1 million adults and adolescents were living with HIV by the end of 2006.[26]The primary means of acquiring infection among adults involves the exchange of body fluids through unprotected sexual intercourse with an infected partner and injection drug use using shared needles and syringes. The virus also can be perinatally transmitted to children born to infected mothers. Since 1985, all donated blood in the United States is screened for HIV. The risk of HIV infection due to transfusion of screened blood products is estimated to be 2 per 1 million units transfused.[27]Screening does not eliminate the potential for a seronegative but infected unit from a recently infected donor to escape detection.

HIV is not transmitted by the airborne route, household or workplace contact with infected persons, exposure to contaminated environmental surfaces, or insect vectors. The virus is easily inactivated by most common disinfectants; including household bleach (diluted 1:10 to 1:100).[1]

Groups of workers at risk for acquiring HIV infection occupationally are HCP and other workers in contact with blood or other body fluids who sustain accidental percutaneous or mucosal inoculations with HIV-infected material. The magnitude of risk depends on the severity of exposure, but, on the average, is about 0.3 percent after percutaneous injury. The risk for infection following mucosal exposures is estimated to be lower, at approximately 0.09 percent. In the absence of direct exposure, HCP are not at occupational risk for HIV infection. In the United States, through December 2006, 57 HCP have been documented as having seroconverted to HIV following occupational exposures.[28]In addition, 140 other cases of HIV infection or AIDS have occurred among HCP who have not reported other risk factors for HIV infection and who report a history of occupational exposure to blood, body fluids, or HIV-infected laboratory material, but for whom seroconversion after exposure was not documented. The number of these workers who acquired their infection through occupational exposures is unknown.

Clinical Features and Laboratory Diagnosis

The clinical course of HIV infection is variable and changing with the advent of antiretroviral therapy and treatment and prophylaxis for infectious complications. Early after infection, within a few weeks to months, an acute flu-like febrile illness characterized by malaise, pharyngitis, lymphadenopathy, maculopapular rash, and headache may occur. At initial presentation of such patients, HIV antibody screening tests (EIA) may be negative, but viral antigen (p24 antigen) and nucleic acid amplification testing (e.g., polymerase chain reaction) allow the diagnosis to be established at this stage.

Following initial infection, most persons have generalized asymptomatic lymphadenopathy and appear well. However, laboratory tests document a gradual decline in the number of circulating T-helper lymphocytes (CD4 cells) beginning soon after infection and continuing over the next several years. T-helper cells are essential components of the immune system and mediate aspects of both cellular and humoral immunity.

In the absence of therapy, symptoms, signs, and illness suggestive of mild to moderate immunodeficiency appear after about 5 years, when CD4 cells decrease by about 50 percent, to less

than 500 cells/mm^3. Intermittent fever, oral thrush, bacterial pneumonia, enteric infections, and reactivated tuberculosis (TB) are typically diagnosed at this time. When CD4 cell counts fall below 200 cells/mm^3, serious opportunistic infections can occur. Pneumocystis pneumonia (PCP) was the most common index diagnosis in the first 5 years of the epidemic, but the advent of effective prophylaxis and highly active combination antiretroviral therapy has decreased the incidence of PCP. The incidence of other opportunistic infections and malignancies, including Kaposi's sarcoma, lymphoma, disseminated TB, toxoplasmosis, and cryptococcal meningitis, also has decreased.

With the exception of TB, the infectious complications of HIV infection generally are not transmissible to healthy persons and pose no risk in the workplace. Indeed, the causative organisms of these complications (e.g., *Candida*and *Toxoplasma*) are ubiquitous, and most adults have already been exposed. Opportunistic infections in HIV-infected patients usually represent reactivation of dormant organisms when the immune system can no longer keep them inactive.

Treatment, Prevention, and Control

Treatment should be offered to all patients with symptoms ascribed to HIV infection and all patients with CD4 cell counts below 350 cells/mm^3.[29]Recommendations for offering antiretroviral therapy in asymptomatic patients requires analysis of many real and potential risks and benefits. Information from clinical trials regarding the treatment of acute HIV infection is very limited. Ongoing clinical trials are addressing the question of the long-term clinical benefit of potent treatment regimens for primary infection. Antiretroviral therapy should also be initiated in pregnant women, patients with HIV-associated nephropathy, and patients coinfected with HBV when treatment is indicated, regardless of CD4 T-cell count. Prior to initiating antiretroviral therapy, all patients should undergo HIV drug-resistance testing (preferably genotype testing in antiretroviral-naive patients) and be screened for HLA-B*5701 before an abacavir-containing regimen is used. If antiretroviral therapy is initiated, the goals of therapy should include maximal and durable suppression of viral load, restoration and/or preservation of immunologic function, improvement of quality of life, and reduction of HIV-related morbidity and mortality.[29]

People at risk for direct contact with blood and other potentially infected materials should receive specific instruction in Standard Precautions, as recommended by the Centers for Disease Control and Prevention (CDC)[1,3,30]and mandated by OSHA.[15]For most environments outside of healthcare settings, common sense and attention to personal hygiene are adequate to protect workers. Gloves should be worn to clean up sites of visible blood contamination. Environmental surfaces can then be decontaminated with disinfectant solutions or household bleach (diluted 1:10 to 1:100).[1]

Postexposure Prophylaxis

Workers sustaining accidental parenteral exposures to HIV should be counseled to undergo baseline and follow-up testing for 6 months after exposure (e.g., 6 weeks, 3 months, and 6 months) to diagnose infection. Since 1996, the U.S. Public Health Service (PHS) has recommended postexposure chemoprophylaxis with antiretroviral agents after certain needlestick, mucous membrane, and nonintact skin exposures to HIV-infected sources that pose a risk of infection transmission (Tables 101-3 and 101-4).[2,31]Most HIV exposures warrant a two-drug regimen using two nucleoside reverse transcriptase inhibitors (NRTIs) or one NRTI and one nucleotide reverse transcriptase inhibitor (NtRTI). Combinations that can be considered for PEP includes zidovudine (ZDV) and lamivudine (3TC) or emtricitabine (FTC); stavudine [d4T] and 3TC or FTC; and tenofovir (TDF) and 3TC or FTC. The addition of a third (or even fourth) drug should be considered for exposures that pose an increased risk for transmission or that

involve a source in whom antiretroviral drug resistance is likely. The PHS recommends that expanded PEP regimens be protease inhibitor (PI)-based. The PI preferred for use in expanded PEP regimens is lopinavir/ritonavir (LPV/RTV). Other PIs acceptable for use in expanded PEP regimens include atazanavir, fosamprenavir, RTV-boosted indinavir, RTV-boosted saquinavir, or nelfinavir. Selection of the PEP regimen should consider the comparative risk of infection represented by the exposure; information about the exposure source, including history of and response to antiretroviral therapy based on clinical response, CD4+ T-cell counts, viral load measurements, and current disease stage; and tolerability of PEP, including the potential toxicity of the regimen. Data from animal models of prophylaxis with these agents suggest that antiviral activity is diminished when treatment is delayed for more than 24 hours. For this reason, immediate reporting and access to chemoprophylaxis is recommended. Testing to determine the HIV infection status of an exposure source should be performed as soon as possible. Use of an FDA-approved rapid HIV-antibody test kit should be considered, particularly if testing by EIA cannot be completed within 24 to 48 hours.[31]

Table 101-3 Recommended HIV Postexposure Prophylaxis for Percutaneous Injuries

Exposure Type	Infection Status of Source				
HIV Positive, Class 1*	HIV Positive, Class 2*	Known Source, Unknown HIV Status†	Unknown Source§	HIV Negative	
Less severe¶	Recommend basic two-drug PEP	Recommend expanded three-drug PEP	Generally, no PEP warranted; however, consider basic two-drug PEP** for source with HIV risk factors†	Generally, no PEP warranted; however, consider basic two-drug PEP** in settings where exposure to HIV-infected persons is likely	No PEP warranted
More severe§§	Recommend expanded three-drug PEP	Recommend expanded three-drug PEP	Generally, no PEP warranted; however, consider basic two-drug PEP** for source with HIV risk factors†	Generally, no PEP warranted; however, consider basic two-drug PEP** in settings where exposure to HIV-infected persons is likely	No PEP warranted

*HIV positive, Class 1—asymptomatic HIV infection or known low viral load (e.g., <1,500 RNA copies/mL). HIV positive, Class 2—symptomatic HIV infection, AIDS, acute seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of postexposure prophylaxis (PEP) should not be delayed pending expert consultation, and, because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.
†Source of unknown HIV status (e.g., deceased source person with no samples available for HIV testing).
§Unknown source (e.g., a needle from a sharps disposal container).
¶Less severe (e.g., solid needle and superficial injury).
**The designation "consider PEP" indicates that PEP is optional and should be based on an individualized decision between the exposed person and the treating clinician.
‡If PEP is offered and taken, and the source is later determined to be HIV negative, PEP should be discontinued.
§§More severe (e.g., large-bore hollow needle, deep puncture, visible blood on device, or needle used in patient's artery or vein).

Table 101-4 Recommended HIV Postexposure Prophylaxis for Mucous Membrane Exposures and Nonintact Skin* Exposures

	Infection Status of Source				
Exposure Type	HIV Positive, Class 1†	HIV Positive, Class 2†	Known Source, Unknown HIV Status§	Unknown Source¶	HIV Negative
Small volume**	Consider basic two-drug PEP†	Recommend basic two-drug PEP	Generally, no PEP warranted; however, consider basic two-drug PEP‡ for source with HIV risk factors§§	Generally, no PEP warranted; however, consider basic two-drug PEP‡ in settings where exposure to HIV-infected persons is likely	No PEP warranted

Large volume[¶¶]	Recommend basic two-drug PEP	Recommend expanded three-drug PEP	Generally, no PEP warranted; however, consider basic two-drug PEP[†] for source with HIV risk factors[§§]	Generally, no PEP warranted; however, consider basic two-drug PEP[‡] in settings where exposure to HIV-infected persons is likely	No PEP warranted

*For skin exposures, follow-up is indicated only if there is evidence of compromised skin integrity (e.g., dermatitis, abrasion, or open wound).
[†]HIV Positive, Class 1—asymptomatic HIV infection or known low viral load (e.g., <1,500 RNA copies/mL). HIV Positive, Class 2—symptomatic HIV infection, AIDS, acute seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of postexposure prophylaxis (PEP) should not be delayed pending expert consultation, and, because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.
[§]Source of unknown HIV status (e.g., deceased source person with no samples available for HIV testing).
[¶]Unknown source (e.g., splash from inappropriately disposed blood).
**Small volume (i.e., a few drops).
[†]The designation, "consider PEP," indicates that PEP is optional and should be based on an individualized decision between the exposed person and the treating clinician.
[§§]If PEP is offered and taken, and the source is later determined to be HIV negative, PEP should be discontinued.
[¶¶]Large volume (i.e., major blood splash).

In addition to follow-up serologic testing, monitoring for PEP toxicity is needed if PEP is taken. A complete blood count and renal and hepatic profiles should be done at baseline and 2 weeks after initiation of PEP. If the PEP regimen includes a PI, the exposed person also should be monitored for hypoglycemia, crystalluria, hematuria, hemolytic anemia, and hepatitis. The PEP regimen should be discontinued or modified and expert consultation obtained if PEP toxicity develops.[31]

Occupational exposure to HIV can be a frightening experience. Consultation with clinicians knowledgeable about HIV transmission risks who can provide supportive counseling to the worker is essential during the follow-up interval. The CDC recommends that occupationally exposed personnel practice safer sex by using condoms correctly and consistently and avoid pregnancy, breastfeeding, and blood and organ donation for 6 months after exposure.[31]

Conclusions

Exposure to bloodborne viruses is a serious concern to HCP. Prevention of transmission of HBV, HCV, and HIV infection in healthcare settings requires a multifaceted approach, including promoting Hepatitis B vaccination of all HCP who may have contact with blood or body fluids, practicing Standard Precautions, and preventing percutaneous injuries. Postexposure management also is an integral component of a complete program to prevent bloodborne virus transmission. Healthcare organizations should make available to their personnel a system that includes written protocols for prompt reporting, evaluation, counseling, treatment, and follow-up of occupational exposures.[2,31]

Recommendations for HBV postexposure management include initiation of the Hepatitis B vaccine series to any susceptible, unvaccinated person who sustains an occupational blood or body fluid exposure. PEP with HBIG and/or Hepatitis B vaccine series should be considered for occupational exposures after evaluation of the HBsAg status of the source and the vaccination and vaccine-response status of the exposed person. Table 101-2 provides guidance for selecting the appropriate HBV PEP.

Immunoglobulin and antiviral agents (e.g., interferon with or without ribavirin) are not recommended for PEP of HCV exposure. For HCV postexposure management, the HCV status of the source and exposed person should be determined, and for HCP exposed to an HCV-positive source, follow-up HCV testing should be performed to determine if infection develops.

Recommendations for HIV PEP include a basic 4-week regimen of two drugs (ZDV plus 3TC or FTC; d4T plus 3TC or FTC; or TDF plus 3TC or FTC) for most HIV exposures and an expanded regimen that includes the addition of a third drug for HIV exposures that pose an increased risk for transmission (Tables 101-3 and 101-4). When the source person's virus is known or suspected to be resistant to one or more of the drugs considered for the PEP regimen, the selection of drugs to which the source person's virus is unlikely to be resistant is recommended.

Occupational exposures should be considered urgent medical concerns to ensure timely postexposure management and administration of HBIG, Hepatitis B vaccine, and/or HIV PEP.

Future Trends

Future directions in the area of management of occupational blood exposures include more systematic (e.g., Internet-based) surveillance of occupationally acquired HBV, HCV, and HIV infection through systems such as the CDC's National Healthcare Safety Network; better definition of the epidemiology of blood contact and the efficacy of preventive measures; development and evaluation of new safety devices and protective barriers; modification/improvement of HIV PEP regimens; and development and evaluation of vaccines for HIV and HCV.

International Perspective

In the international arena, the same risk factors and prevention strategies apply to occupational blood exposures and bloodborne virus transmission. However, countries with the highest prevalence of HBV, HCV, and HIV infection often have limited resources for infection prevention, sterile supplies, personal protective equipment, occupational exposure management, and PEP.[32]This may result in greater opportunity for occupational exposures and infection transmission.

Preventive strategies for international HCP are important because the likelihood that these workers will interact with patients with HBV, HCV, and HIV infection is high. As in the United States, strategies for prevention of occupational bloodborne virus infection include (1) Hepatitis B vaccination; (2) routine use of barriers such as gloves, gowns, and eye protection; (3) careful handling of sharp instruments and use of devices with safety features; and (4) provision of exposure management, including PEP, as appropriate.[31]

A number of special challenges exist in international settings. Scarce resources influence which prevention strategies will be adopted in healthcare settings. Strategies for changing behaviors of HCP to handle and dispose of sharps safely and use barrier precautions need to be culturally appropriate. Finally, the stigma of bloodborne virus infection, particularly HIV infection, influences the willingness of HCP to be tested after occupational exposure and complete follow-up for occupational exposure management.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Volunteers, Contract Workers, and Other Nonemployees Who Interact with Patients

Author(s): Sue Sebazco, RN, MBA, CIC
Director of Infection Control and Employee Health & Education

Texas Health
Arlington, TX

Published: October 3, 2014

Abstract

Many individuals who are not employees of the healthcare facility may come into contact with patients. For the purpose of this chapter, these nonemployees are individuals who do not receive compensation from the healthcare facility or appointment recognition or have direct care student status in the hospital environment but do have a relationship with the organization to perform specific services.

As with the volunteer or contract worker, a nonemployed individual will provide services at the request and with the approval of the healthcare facility. This designation indicates that the facility is aware of and has approved their activities. Therefore, the healthcare facility has the responsibility to establish safe practice policies and procedures for these groups. This difference is in contrast to others such as a patient's own spiritual leader or a friend who stays with a patient and assists the patient or provides support at the patient's request or invitation. Thus, family members and friends of the patient are not included in the status of nonemployed individuals.

Healthcare industry representatives, contracted sitters, contract construction workers, volunteer community clergy, pet therapists, and volunteers are examples of nonemployee individuals who may interact directly or indirectly with patients during their inpatient stay. These individuals provide a variety of necessary services, such as delivering mail, flowers, or personal care items to the patients' bedsides; transporting patients within the facility; providing spiritual support or comfort; providing education or observation; and staffing the gift shop and visitor waiting areas.

All nonemployee individuals permitted to function at the facility who have direct contact with patients and visitors must understand the transmission and prevention of disease within the framework of their duties to reduce the risk for exposure to potential pathogens. Each facility should establish a plan for protecting approved nonemployee individuals that includes a list of allowed and prohibited duties;

evidence of an initial two-step tuberculosis skin test and annual tuberculin skin test guided by the facility's annual tuberculosis risk assessment and individual state laws; a health history that includes immunization status; education about Standard Precautions, infection prevention practices in specific areas such as the operating room, tuberculosis, and bloodborne pathogens; and the risks of exposure to communicable diseases and prevention.

Key Concepts

- Nonemployee individuals must understand the transmission and prevention of disease within the framework of their duties to reduce the risk for occupational exposure to potential pathogens.
- Nonemployee individuals must be compliant to requests for prescreening health records including immunizations and tuberculosis screening.
- Nonemployee individuals who have more sustained contact with patients may require more intensive training in exposure prevention specific for their function.
- The types of individual tasks, environments, or patient contacts should be carefully evaluated along with the associated expected risk.
- It is critical to ensure the competency of volunteers, contracted personnel, and other nonemployee staff as they perform their assigned duties with patients.

Background

Declining financial resources, population aging, and increasing public expectations mark today's healthcare environment. Hospitals have historically used volunteers and other nonemployees to provide a variety of cost-effective and sometimes unique services to improve the quality of patient care. Some of the services that these individuals may provide range from casual contact to more direct patient contact in high-risk areas.[1]Casual contact occurs when delivering items to the patients, providing direction, and working in the gift shop.[2]Direct patient contact happens when transporting patients within the facility and visiting with patients to provide spiritual or emotional comfort. Technical and sales personnel may work in the operating room or specifically with a patient to provide a service such as fitting an adaptive device or a wheelchair. Those volunteers and nonemployees of the hospital providing services to patients and visitors must understand the transmission and prevention of disease within the framework of their duties to reduce the risk for occupational exposure to potential pathogens. The types of services or patient contact should be carefully evaluated, along with the associated expected disease transmission risk.

Basic Principles

There are few published guidelines that address the protection of nonemployee individuals in the healthcare setting. This literature most often is related specifically to those individuals referred to as volunteers. After literature review, there were no documented cases of infection in volunteers or other nonemployee individuals from an exposure to communicable disease in the healthcare setting but the possibility does exist as these individuals provide more services and interact more with patients and the healthcare facilities.

In December 1991, the Occupational Safety and Health Administration (OSHA) published a safety and health standard on managing bloodborne pathogens in the workplace. The standard was designed to reduce the possibility of healthcare personnel (HCP) exposure to blood or other potentially infectious fluids, but the standard leaves unspecified whether unpaid personnel are included in the regulation.[3,4]

In the original and 2005 updated Centers for Disease Control and Prevention (CDC) *Guidelines for Preventing the Transmission of Mycobacterium Tuberculosis in Health-Care Settings*, recommendations apply to all paid and unpaid employees.[4,5]Both publications state, "The term HCWs refers to all paid and unpaid persons working in health-care settings who have the potential for exposure to *M. tuberculosis*."[4,5]The purpose of these documents is to provide recommendations that will reduce the transmission of tuberculosis (TB) in healthcare facilities.[4]The CDC's November 4, 2005, publication *Controlling Tuberculosis in the United States*advises that education and TB prevention activities are based on the level of TB risk identified for the facility's area.[6]TB screening should be included for those HCP who enter patient rooms or treatment rooms regardless if the patient is present.[5]Additionally, in the *Infection Control Guidelines for Home Health Care*, volunteers are specifically referred to in relationship to TB exposure control. These guidelines may provide the base for a volunteer service plan for the prevention of exposure to all communicable diseases.[2]

Nonemployee individuals who have more sustained or specialized contact with patients may require more intensive training in exposure prevention. Therefore, understanding the tasks of these individuals is essential to establishing a plan for the protection of both nonemployee HCP and the patients during their services.

THE PLAN FOR NONEMPLOYEE HEALTHCARE PERSONNEL SERVICES

Each facility should establish a plan for the protection of nonemployee HCP and for the protection of the patient and other staff consisting of the following:

- A listing of duties that nonemployee HCP are permitted to perform and not permitted to perform. Nonemployee HCP must know that he or she has the right to refuse to perform activities that may cause undue risk for communicable disease exposure, whether they have or have not been trained in that activity.
- Transporting specimens and used procedure trays. In some facilities, nonemployee HCP may be responsible for transporting specimens and used procedure trays. Nonemployee HCP must be instructed to transfer specimens and procedure trays according to healthcare setting policy. Nonemployee HCP should not transport specimens that are not appropriately contained in a closed bag or container.
- Contact with blood or body fluid. Nonemployee HCP are not to engage in tasks that necessitate contact with items or surfaces visibly soiled with blood or other body fluids, but should be instructed to notify appropriate personnel for cleanup.
- Special precautions. Nonemployee HCP should not enter rooms with infection prevention Transmission-based Precautions signs or with a special sign (e.g., "check with nurse before entering room") without consulting with the nurse caring for that patient or another designated authority.
- Nonemployed HCP must be included in the facility's TB control plan. If the individual is associated with an industry or contract service such as construction, the contract should include the requirement for TB screening. If the individual is a volunteer, the healthcare facility should provide that testing or

at least require the volunteer to provide appropriate documentation from his or her primary care provider, health department, or other designated healthcare professional. Regardless of who actually does the testing, before assignment, a two-step tuberculin skin test (TST) or a single blood assay for *Mycobacterium tuberculosis*(BAMT) test should be completed on all HCP independent of setting or risk to provide a baseline.[5]Annual serial TB testing is based on the healthcare setting's risk assessment classification and individual state laws.[5,6]HCP in low-risk settings should have follow-up testing only if an unprotected exposure occurs with an infectious TB patient unless otherwise stated in state health law.[5]This test should be completed by the employee/occupational health department, by the facility designee, or by the company or contract service of record for the individual. Nonemployee HCP with a previously positive TST or with a history of treated TB should not have a skin test but should provide documentation of an assessment for reactivation as well as continue with a follow-up process similar to that required for employed HCP. Documentation of reactive TST from a healthcare provider should be kept on file. "HCWs who work in a health-care setting but do not receive payment from that setting should receive baseline training TB infection prevention policies and procedures, the TB screening program, and procedures for reporting an *M. tuberculosis*infection test conversion or diagnosis of TB disease."[5]

- Nonemployee HCP should be given initial and annual education about Standard Precautions and Transmission-based Precautions, including hand hygiene[7]and respiratory hygiene/cough etiquette,[8] tuberculosis,[5]bloodborne pathogens,[3]risk for exposure to communicable diseases, and prevention and infection prevention policies and procedures related to the scope of their assignment.
- Consideration should be given to requiring all nonemployee HCP to provide documentation of a preplacement assessment containing health history, immunizations, and prior exposure to communicable diseases.

EXPOSURE PREVENTION

In addition to the tremendous emotional burden that is carried by an individual exposed to another's blood or body fluid, exposure follow-up consumes considerable time, money, and resources for the healthcare facility. It is more useful to prevent the exposure from occurring. The following measures may be taken to reduce the risk for exposure:

- Adopt policies that decrease exposures, including engineering controls.
- Teach nonemployee HCP to follow the standard and transmission-based isolation guidelines as established by the facility, including appropriate use of personal protective equipment (PPE).
- Educate nonemployee HCP on the signs and symptoms that would indicate the need to stay home to prevent the spread of infectious conditions.[5]

Any nonemployee HCP exposed to blood or body fluids must immediately report the exposure. Based on contract or service agreement, the exposed individual should report to his or her supervisor in the facility or the HCP's home company completes an incident report and follows the process as established by the healthcare facility. During orientation, and annually thereafter, the nonemployee should be taught the appropriate reporting mechanism to facilitate postexposure workup. Postexposure follow-up should follow the guidelines established by employee/occupational health services.

HEALTH REQUIREMENTS

Health requirements should reflect the policies of the facility for all employees. As part of the plan, the following health requirements should be reviewed with all nonemployee HCP during orientation:

1. Any nonemployee HCP with a draining skin lesion, including fever blisters, should not have contact with patients and should not handle patient care equipment.
2. Nonemployee HCP are to exclude themselves from the hospital if they experience symptoms of respiratory or gastrointestinal infection or other infectious diseases until the condition resolves.
3. Any questions regarding illness and the performance of services should be directed to the director of the department where services are rendered or the director's designee, infection prevention representative, or to employee health services.
4. Nonemployee HCP should be educated on vaccines available for their protection.
5. Nonemployee HCP who have a risk for exposure to blood or body fluids should be eligible to receive the Hepatitis B vaccine provided by the facility or via their employer's occupational health program as detailed in the Bloodborne Pathogen Standard.[3]
6. Influenza vaccine is strongly recommended for individuals in close contact with persons in high-risk groups, HCP, and those older than 65 years of age. Therefore, nonemployee HCP should be encouraged to receive the vaccine.[9]
7. Nonemployee HCP older than 65 years of age and those who meet the other high-risk criteria for illness should receive a pneumococcal vaccine following current vaccine recommendations.[10,11]
8. Nonemployee HCP should be immune to measles, mumps, and rubella. Laboratory evidence or physician documentation of measles, mumps, and rubella immunity should be obtained.[11,12,13]
9. Varicella vaccine is recommended for the nonimmune and those who have contact with high-risk individuals. This would include HCP and nonemployee HCP who have contact with at-risk patients.[12,14]
10. One-time administration of one dose of tetanus, diphtheria, and acellular pertussis vaccination is recommended for all HCP with direct patient contact.[12,15]Nonemployee HCP should also be considered for this vaccine if their job duties would involve direct patient contact.

Other vaccines may be desirable depending on the volunteer's role in the facility and federal or state regulations.

HEALTHCARE INDUSTRY REPRESENTATIVES

The Health Industry Representative Association defines a healthcare industry representative (HCIR) as "an individual who sells, promotes, and gives training and advice concerning medical devices, systems and procedures."[16]These individuals have seen their roles greatly expand as technology advances.

These representatives may typically be present in the operating room but should not scrub, be allowed in the sterile field, or be involved in direct patient care. Therefore, the function of the HCIR requires additional scrutiny related to duties. These individuals are subject to the same standards as other nonemployee HCP but require additional education in the following areas:

1. Concepts of a sterile field
2. Aseptic principles
3. Biohazardous waste
4. Fire, laser, and electrical safety
5. Facility-specific emergency codes and evacuation procedures
6. Operating room traffic patterns and general practices[17,18]

7. Dress code and other hygiene recommendations
8. Operating room policies for bringing in instrumentation and devices

Some medical companies provide training courses for their employee HCIRs; however, the program should be evaluated by the facility to ensure that education is adequate for the hospital setting. Additionally, the Association of preOperative Registered Nurses (AORN) does endorse an online training course that these individuals can complete for needed education.[16]The hospital may also use one of the commercial or self-developed tracking systems for HCIRs, which allows the representatives to log in officially as an HCIR, receive identification tags for each day they are in a facility, and perform required system education and verification of passing scores before working in the facility and specialty areas.

EDUCATION FOR NONEMPLOYEE HEALTHCARE PERSONNEL

Education is extremely important to eliminate the risk for exposure to communicable diseases. Following the guidelines for education and training, found in another section of this text, effective educational programs should be developed and provided. Orientation should be conducted before assignment. This education should be developed and prepared by the infection prevention department and should include the following:

- Infection prevention policies and procedures
- Modes of infection transmission
- Bloodborne pathogen exposure prevention
- TB information
- Hand hygiene
- Other state or local regulatory requirements
- Processes for reporting of unsafe situations, including recognized breaches in infection prevention processes

An initial and annual infection prevention education program for all active nonemployee HCP must be done. The healthcare setting should have a method to determine that those employed by outside agencies are compliant with current education and training requirements or are responsible for training them through the facility's current infection prevention and control education program.[9]Education must include facility-specific policies and practices to ensure the safety of both the individual and the patient. Competency training and checklists for specific procedures may be helpful in ensuring the standard of care.

Conclusions

Volunteers and other nonemployee HCP are an important part of many healthcare organizations. With the increasing demands on the healthcare environment, the skills of the nonemployee HCP are valuable resources that can often improve the quality and delivery of the patient care. Education in infection prevention and support is needed to protect both the nonemployee HCP and their contacts. Evaluation of the nonemployee HCP duties and risks can assist in developing an education plan to maintain a safe work environment.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Immunization of Healthcare Personnel

Author(s): Valerie Sparks, BSN, CIC
Infection Control Coordinator

Midland Memorial Hospital
Midland, TX

Published: October 3, 2014

Abstract

*Immunization is the most effective means of preventing Hepatitis A and B; influenza; measles, mumps, and rubella; polio; pertussis, tetanus, and diphtheria; varicella; and other vaccine-preventable diseases. In medical institutions, susceptibility among healthcare personnel to vaccine-preventable diseases can have devastating consequences. Any medical facility or organization that provides direct patient care is encouraged to formulate a comprehensive immunization policy for all healthcare personnel, as indicated by the Centers for Disease Control and Prevention (found at **http://www.cdc.gov/vaccines/adults/rec-vac/hcw.html**) and by the Advisory Committee on Immunization Practices (found at **http://www.cdc.gov/vaccines/acip/**).*

Key Concepts

- An overview of the guidelines for immunization of healthcare personnel.
- A brief review of the basic principles of immunization and misconceptions regarding immunizations.
- Review of specific vaccines pertinent to healthcare personnel.
- Basic information necessary to establish a healthcare personnel immunization program.
- A listing of general resource material and additional information on these issues.

Background

Immunization is the most effective means of preventing Hepatitis A and B; influenza; measles, mumps, and rubella; polio; pertussis; tetanus-diphtheria; varicella; and other vaccine-preventable diseases. Unfortunately, adults who escape immunization at the recommended time in childhood often fail to attain adequate protection later in life. In medical institutions, susceptibility among healthcare personnel (HCP)

to vaccine-preventable diseases can have devastating consequences. HCP who acquire vaccine-preventable disease not only suffer morbidity and mortality as a result of infection, but also serve as vectors for transmitting disease to other staff members and patients. Outbreaks of vaccine-preventable diseases have been well documented in medical institutions.[1,2,3,4] In these situations, if high-risk patients are exposed and become infected, substantial morbidity and mortality may occur. Once an outbreak is under way, the cost of emergency measures to control vaccine-preventable outbreaks within institutions can be enormous and disruption of vital hospital routines burdensome. Current trends in healthcare cause concern that similar transmission of vaccine-preventable diseases can occur in home health and long-term care settings and community settings (health clinics, etc.). The fact that these outbreaks can be prevented by immunizing HCP against vaccine-preventable diseases should serve as strong motivation for an effective immunization program.

The purpose of this chapter is to provide an overview of the guidelines for immunization of HCP. The chapter starts with a brief review of the basic principles of immunization and misconceptions regarding immunizations. Specific vaccines pertinent to HCP are outlined and the basic information necessary to establish an HCP immunization program is presented. A listing of general resource material and additional information on these issues can be obtained from the resources identified at the end of the chapter.

The Centers for Disease Control and Prevention (CDC) has published guidelines for the immunization of HCP.[5] In this document it states, "Any medical facility or organization that provides direct patient care is encouraged to formulate a comprehensive immunization policy for all HCP."[5]

The CDC further defines HCP as "all paid and unpaid persons working in health-care settings who have the potential for exposure to patients and/or to infectious materials, including body substances, contaminated medical supplies and equipment, contaminated environmental surfaces, or contaminated air. HCP might include (but are not limited to) physicians, nurses, nursing assistants, therapists, technicians, emergency medical service personnel, dental personnel, pharmacists, laboratory personnel, autopsy personnel, students and trainees, contractual staff not employed by the health-care facility, and persons (e.g., clerical, dietary, housekeeping, laundry, security, maintenance, administrative, billing, and volunteers) not directly involved in patient care but potentially exposed to infectious agents that can be transmitted to and from HCP and patients."

Basic Principles

DEFINITIONS

Definitions of key terms used in this chapter can be found in Table 103-1. These definitions are derived from the 2011 update published by the Advisory Committee on Immunization Practices (ACIP).[5] The terms vaccination and immunization are often used interchangeably. "Vaccine" is derived from vaccinia, a virus that was used in smallpox vaccines. Thus, "vaccination" actually refers to the prevention of smallpox, whereas "immunization" is a broader term that encompasses the use of any immunobiologic to prevent infectious diseases by inducing immunity. An "immunobiologic" is the antigenic substance or antibody-containing preparation used to induce or produce immunity.

- Immunity may be induced by either active or passive methods. Active immunization involves the development of antibodies or cellular immune response following administration of a vaccine or toxoid.

- Vaccines consist of live (usually attenuated, i.e., "weakened") or inactivated microorganisms or fractions thereof. Toxoids are modified bacterial toxins. Inactivated or killed immunobiologics may consist of the whole microorganism (whole cell pertussis), detoxified exotoxins (diphtheria and tetanus toxoids), soluble capsular material (pneumococcal polysaccharide), surface antigen (Hepatitis B), or components of the organism (subunit influenza).
- For some diseases such as influenza, measles, and polio, both live and inactivated vaccines have been or currently are available. Live, attenuated vaccination involves the use of very small doses of living organisms, which have been weakened to produce a subclinical infection. Consequently, this approach more closely approximates the immunological response that follows natural infection and may confer more long-lasting immunity than the use of killed organisms. Thus, a single dose of measles, mumps, and rubella (MMR) vaccine is thought to confirm lifelong immunity (even though two doses are now recommended), whereas repeated vaccination and boosters are required for other immunobiologics such as diphtheria and tetanus.
- Passive immunization, on the other hand, refers to the temporary immunity that follows exogenous antibody administration. Sources of antibodies include:
  - Human immunoglobulin (IG)
  - Specific immunoglobulin preparations (e.g., Hepatitis B immune globulin [HBIG])
  - Antitoxins (e.g., diphtheria or botulinum antitoxin). These antibody preparations are harvested from pooled human blood plasma or occasionally derived from the serum of immunized animals.

Table 103-1.Glossary of Terms[5]

Table 103-1 Glossary of Terms

Immunobiologic	Antigenic substance or antibody containing preparation used to induce immunity and prevent infectious disease.
Active immunization	Use of an antigenic substance to induce immunity by stimulating an immune response. Vaccine: A suspension of live (usually attenuated) or inactivated microorganisms, or fractions thereof. Toxoid: A modified (nontoxic) bacterial toxin that is capable of stimulating antitoxin formation.
Passive immunization	Use of an antibody-containing preparation to enhance or restore immunity. Immunoglobulin (Ig): A sterile solution containing antibodies from human blood. Antitoxin: A solution of antibodies derived from the serum of animals immunized with specific antigens.
Vaccine	A vaccine consisting of a single strain or type of organism.
Monovalent	A vaccine consisting of three types or strains of a single organism (e.g., influenza vaccine), or three different organisms (e.g., diphtheria-pertussis-tetanus vaccine).
Trivalent	An influenza vaccine consisting of four influenza strains (e.g., two A virus strains, two B virus strains).
Quadrivalent	Multiple strains or types of organisms in the vaccine (e.g., 23-valent pneumococcal vaccine).
Polyvalent	

TYPES OF IMMUNOBIOLOGICS

Table 103-2 lists the routine vaccines applicable for use in HCP. Items to note include:

- Immunobiologics produced by different manufacturers contain unique active and inert ingredients.
- Suspending fluids may consist of sterile water, saline, or complex fluids plus small amounts of protein or other constituents from the biological system in which the vaccine was produced.
- Preservatives, antibiotics, and stabilizers are used to inhibit bacterial growth or stabilize the active component of the immunobiologic.
- Adjuvants such as aluminum phosphate enhance the antigenicity of immunobiologics such as toxoids and Hepatitis B vaccine, which, if administered alone, would not elicit a sufficient immunological response.
- The clinical relevance of these components is addressed in subsequent portions of this chapter.

Table 103-2.Currently Available Vaccines Used in HCP*[5]

Table 103-2 Currently Available Vaccines Used in HCP*

Vaccines	Recommendations in brief
Hepatitis B	If HCP do not have documented evidence of a complete Hepatitis B vaccine series, or if HCP do not have an up-to-date blood test indicating immunity to Hepatitis B (i.e., no serologic evidence of immunity or prior vaccination) then: • Offer the three-dose series (the first dose now, the second dose in 1 month, the third dose approximately 5 months after the second dose). • Offer anti-HBs serologic tested 1 to 2 months after the third dose.
Influenza	One dose of influenza vaccine annually.
Measles, Mumps, and Rubella (MMR)	HCP born in 1957 or later and have not had the MMR vaccine, or HCP without an up-to-date blood test indicating immunity to measles, mumps, and rubella (i.e., no serologic evidence of immunity or prior vaccination), should receive two doses of MMR, 4 weeks apart. Documentation of provider-diagnosed disease is not considered acceptable evidence of immunity for measles, mumps, or rubella. The CDC has added laboratory confirmation of disease as acceptable presumptive evidence of immunity for all HCP. Adults born before 1957 generally are considered immune to measles and mumps.
Varicella (chickenpox)	HCP without written documentation confirming two doses of vaccine, laboratory evidence of immunity, or laboratory confirmation of disease; or diagnosis of history of varicella disease by healthcare provider; or diagnosis of history of herpes zoster by healthcare provider are considered nonimmune and should receive two doses of varicella vaccine administered 4 to 8 weeks apart.
Tetanus, Diphtheria, Pertussis (Tdap)	HCP, regardless of age, should receive a single dose of Tdap as soon as feasible if they have not previously received Tdap. HCP should receive Td boosters every 10 years. Tdap is recommended for pregnant HCP during each pregnancy.
Meningococcal	Microbiologists who are routinely exposed to isolates of *N. meningitidis*should get one dose and boost every 5 years if risk continues.

*HCP include physicians, nurses, emergency medical personnel, dental professionals and students, medical and nursing students, laboratory technicians, pharmacists, hospital volunteers, and administrative staff.

EFFICACY AND COST-BENEFIT ANALYSES

When used appropriately, immunobiologics prevent infection in the majority of otherwise healthy adults (see Table 103-3 for vaccine efficacy and cost analysis). Using these efficacy rates, Williams and colleagues concluded that widespread immunization programs for adults are cost effective because the cost of immunization is usually much less than the cost of treating a preventable disease.[6]

Table 103-3.Vaccine Efficacy and Cost Analysis[6]

Table 103-3 Vaccine Efficacy and Cost Analysis

Vaccine	Efficacy*	Cost Savings
Hepatitis A	~95 to 100 percent	No data available, but disease is very prevalent
Hepatitis B	85 to 95 percent	Yes, in HCP, due to preventable infections (4,411 episodes/100,000 workers over 5 years) and deaths
Influenza	90 percent	Yes, in patients >65 years of age, due to virus-preventable deaths (20,000/year) and hospitalizations (80,000/year)
Pneumococcus	60 to 95 percent	Yes, in high-risk persons, benefit: cost ratio is 2.32:1
Polio	~100 percent	Yes
Measles and rubella	95 to 98 percent	Yes, in all persons, average benefit: cost ratio for immunization programs is 10:1
Tetanus-diphtheria	95 to 100 percent	No data, but immunization costs very low
Varicella	70 to 90 percent	Yes*

*Defined as the ability to prevent disease in young, healthy adults.

Immunobiologics are also highly cost effective for HCP, who may be at increased risk of disease themselves and/or of transmitting disease to high-risk patients.

For influenza vaccine, enormous cost savings have been projected for elderly adults (>65 years), with 50 to 75 percent effectiveness in reducing deaths of institutionalized high-risk adults. A significant reduction in the number of respiratory illnesses, sick leave, and medical expenditures in healthy working adults who received flu vaccine has been demonstrated,[7]as well as the cost effectiveness in elderly community-dwelling adults.[8]A recent cost-benefit analysis among HCP in the United Kingdom was conducted to determine if it was worth vaccinating HCP against influenza for protection of high-risk

patients. Conclusions were: (1) vaccination was highly effective in HCP, with minimal adverse effects; (2) patient mortality was reduced after vaccinating HCP; and (3) vaccinating was cost saving.

Cost-benefit analyses of pneumococcal vaccine demonstrate that the vaccine is clearly cost effective in high-risk groups. Assuming 60 percent efficacy and 60 percent coverage in high-risk groups, 12,000 deaths could be prevented annually. Patrick and Woolley calculated a benefit-cost ratio of 2.32:1 for high-risk groups consisting of patients aged 50 years or older; patients with chronic diseases of the heart, liver, lungs, or kidneys; and those with diabetes mellitus.[9]

The average benefit-cost ratio for widespread measles and rubella immunization programs, including children, exceeds 10:1. Savings are only slightly reduced by the use of the trivalent vaccine MMR in place of the single-virus vaccine.[10]The savings may be even greater for medical staff and hospital personnel, if they are frequently exposed to these diseases.[3]

Cost-benefit analyses are not available for tetanus and diphtheria toxoid use in adults, but immunization is likely to be cost effective because of the low acquisition cost of this immunobiologic.

More recently, the cost effectiveness of various interventions commonly used in older persons has been published, and both influenza and pneumococcal immunization were found to be among the most cost-effective interventions performed.

MISSED OPPORTUNITIES FOR DISEASE PREVENTION

A recurring theme in outbreaks occurring in medical institutions is the failure of physicians, nurses, medical students, interns, and residents as well as nursing, dental, pharmacy, and other allied health students to obtain recommended immunizations. Even when medical institutions require immunization and make immunobiologics available to physicians and staff members, compliance is often poor. Therefore, special efforts must be made if high HCP immunization rates are to be achieved. The CDC has published comprehensive guidelines on immunization of HCP.[5]More recently, multiple professional societies have called for mandatory immunization of HCP with influenza vaccine.[7,8,9,10,11,12,13,14,15,16,17]

MISCONCEPTIONS AND MISPERCEPTIONS REGARDING IMMUNIZATION

Like most adults, HCP can cite a number of excuses for not obtaining adequate immunization. HCP may view immunizations as "kid stuff," or an imposition on their busy schedules, or unnecessary. For this reason, strong immunization programs and requirements are necessary.

Contraindications

As a result of their exposure to medical information, HCP may have exaggerated fears regarding known adverse reactions or potential complications that have not yet been described. Some may be incorrectly concerned about getting the disease from the vaccine (e.g., influenza, measles). In addition, HCP are concerned about hypersensitivity reactions, viral replication, and efficacy and cost-benefit issues. Although there are some legitimate contraindications to immunization, there remains substantial confusion regarding appropriate indications and exclusions for various vaccines. ACIP compiled a list of common misconceptions concerning contraindications, many of which may apply to HCP (Table 103-4). Finally, there are "anti-vaccine" groups that publish and distribute erroneous or misguided information. Sometimes estimates regarding side effects are exaggerated, yet have some basis in fact, so that even HCP can be influenced by this information.

Table 103-4 Misconceptions Concerning Contraindications to Immunization

Previous local reaction or fever after tetanus-diphtheria (Td) vaccination
Egg intolerance or allergy to feathers
Penicillin or other, nonspecific allergy
Mild acute illness with low-grade fever
Recent exposure to infectious disease
Breastfeeding

Adverse Reactions

Unpleasant childhood and young adulthood memories of redness, soreness, and/or fever may prevent adults from seeking re-immunization. Local reactions and low-grade temperatures are associated with bacterial vaccines, such as tetanus-diphtheria (Td) vaccine. These are usually transient and should not preclude further use, providing recommended dosing guidelines are followed. Urticarial or anaphylactic reactions are very rare complications of vaccines and warrant skin testing to confirm the presence of hypersensitivity.

MMR is generally well tolerated. Data from immunization programs reveal that, even though up to one-half of susceptible HCP experience reactions following rubella or MMR vaccination, these reactions are mild and transient. MMR vaccines may cause fever after vaccination, with the measles component most often associated with this adverse event.[18]Occasional and transient rashes also occur.

Hepatitis B vaccine is also well tolerated. Adverse effects consist primarily of soreness at the injection site and, to a lesser extent, mild systemic symptoms (e.g., fever, headache, fatigue, and nausea). In one vaccination program involving the administration of Hepatitis B vaccine to >100 HCP, local reactions occurred within an hour after injection in >50 percent of recipients and systemic reactions in <10 percent. Adverse reactions were generally mild in severity, and no vaccine recipients missed work because of adverse reactions.[5]

HCP may be reluctant to obtain influenza vaccination because of misgivings about adverse effects. Vaccine candidates may recall the association of Guillain-Barré syndrome (GBS) with the swine influenza immunization program in 1976. Whether this was a temporal relationship or a true cause-and-effect association is hard to know. One report suggested a temporal relationship between influenza vaccine and GBS for vaccines used in 1992 to 1993 and 1993 to 1994 in persons <65 years of age.[19]The risk was on the order of one GBS case per million doses delivered.

Current formulations are well tolerated and are associated with a 3 to 5 percent incidence of local tenderness or low-grade fever. One study in persons >65 years old found that the only side effect in influenza versus placebo vaccine recipients was a transiently sore arm. There was no increased incidence of side effects such as fever, cough, coryza, fatigue, myalgia, headache, nausea, or disability in vaccine recipients compared with placebo recipients.[19]

Pneumococcal vaccine is well tolerated. Minor local side effects such as tenderness and redness are common and reversible within 48 hours. Low-grade fever may occur within the first 24 hours after injection. Other reactions are rare with a systemic reaction rate <1 percent.

Varicella vaccine is also well tolerated, although up to 5 percent of susceptibles may develop a rash and 10 percent a low-grade fever.

Hepatitis A vaccine is very well tolerated with a benign side effect profile.

Lack of a sore arm does not imply that a good antibody response has not resulted. Sore or red arms should be treated symptomatically with ice packs, elevation, and anti-inflammatory medication as needed. Very large or severe local reactions could imply an allergic or Arthrous-type reaction and is best assessed by an allergist or experienced vaccinologist.

Hypersensitivity Reactions

True hypersensitivity reactions are unusual. Potential vaccine allergens include animal proteins, antibiotics, preservatives, and stabilizers. Of these, the most common potential allergen is residual egg protein found in vaccines grown in chick embryo cell cultures (e.g., mumps, measles, or influenza vaccines). Thus, MMR and influenza virus vaccines are contraindicated in persons with histories of anaphylaxis or immediate reactions (e.g., hives, swelling of the mouth and throat, difficulty breathing, hypotension, or shock) following egg ingestion. ACIP points out that there is no evidence that persons with other types of reactions associated with egg ingestion or allergy to chickens or their feathers are at increased risk of reaction following vaccination.

Antibiotics used to prevent bacterial growth in vaccines may also serve as allergens. For example, MMR has trace amounts of neomycin and is contraindicated in patients with histories of anaphylaxis. It should be noted, however, that the usual type of neomycin hypersensitivity is contact dermatitis—a type of delayed or cell-mediated immune response that does not predict anaphylaxis and is not a contraindication to immunization. Fortunately, commercially available immunobiologics do not contain penicillin or its derivatives, the most common cause of antibiotic allergy.

Thimerosal, a mercury-derived preservative, is rarely implicated as a cause of allergic reactions. Persons with histories of hypersensitivity to mercury derivatives are at increased risk for this reaction. The American Academy of Family Physicians, American Academy of Pediatrics, ACIP, and the Public Health Service issued a joint statement in 1999 with the goal of removing or greatly reducing the amount of thimerosal in vaccines. These groups recommend continuation of the current policy of moving rapidly to vaccines that are free of thimerosal as a preservative. Great progress has been made in this regard. Until an adequate supply of each vaccine is available, use of vaccines that do contain thimerosal as a preservative is acceptable.[20]Thimerosal is currently found in several adult vaccines, most in trace amounts (Table 103-5). Employees can be screened for allergy to thimerosal by history (i.e., a previous reaction to a thimerosal-containing vaccine or thimerosal-containing eye drops).

Table 103-5.Thimerosal and Expanded List of Vaccines (updated June 20, 2012): Thimerosal Content in Currently Manufactured U.S. Licensed Vaccines[20]

*Thimerosal is approximately 50 percent mercury (Hg) by weight. A 0.01 percent solution (1 part per 10,000) of thimerosal contains 50 µg of Hg per 1-mL dose or 25 µg of Hg per 0.5-mL dose.

†Sanofi Pasteur's Tripedia may be used to reconstitute ActHib to form TriHIBit. TriHIBit is indicated for use in children 15 to 18 months of age.

‡This vaccine is not marketed in the United States.

§COMVAX is not licensed for use in infants younger than 6 weeks of age because of decreased response to the Hib component.

||Children under 3 years of age receive a half-dose of vaccine, i.e., 0.25 mL (12.5 µg mercury/dose.)

Precautions

A precaution is a condition in a potential vaccine recipient that might increase the risk for either a serious adverse event or that might compromise the ability of the vaccine to produce immunity in the recipient. The 2011 ACIP General Recommendations on Immunization include precautions as a category in their table entitled "Contraindications and Precautions to Commonly Used Vaccines." Examples of precautions include moderate or severe acute illness with or without fever, pregnancy, previous history of GBS, receipt of an antibody-containing product within a certain time period of vaccination, and immunosuppression. ACIP includes "moderate or severe acute illness with or without fever" as a precaution for all vaccines. The decision to delay or administer a vaccination because of moderate or severe illness should be made after assessing the severity of symptoms and etiology of the disease. When a precaution is listed, the vaccination may be deferred until the condition is resolved (e.g., moderate or severe illness is present) unless the benefit of protection from the vaccination outweighs the risk of an adverse reaction.[18]

Viral Replication

It is theoretically possible for live virus vaccines to replicate in an uncontrolled manner in humans; however, this complication is highly unlikely except in persons with altered immune competence. Thus, live vaccines should be avoided in adults with malignancy, symptomatic human immunodeficiency virus (HIV) infection, treatment-induced immune suppression, and similar conditions whenever possible. An exception to this general rule, however, is that according to ACIP guidelines, MMR is recommended for patients with asymptomatic HIV infection who do not have evidence of severe immune suppression (see MMR section) and should be considered for those with symptoms because of the morbidity and mortality of measles infections. Inactivated vaccines (e.g., diphtheria and tetanus toxoids) are not problematic for persons with altered immune competence. Importantly, mild acute illness with low-grade fever and recent exposure to infectious disease are not contraindications for immunization in an otherwise healthy individual.

Breastfeeding and Pregnancy

Female HCP may have concerns regarding immunization during breastfeeding and pregnancy. Breastfeeding should not interfere with routine immunization. According to ACIP, the only vaccine virus that has been isolated from breast milk is rubella, but there is no evidence that such breast milk is harmful to infants or leads to transmission of disease.

On the other hand, pregnancy and the likelihood of pregnancy within 28 days are contraindications to the use of live, attenuated viral vaccines when indicated. Pregnancy is also a contraindication to the use of MMR and varicella vaccines; however, there is no evidence of congenital rubella syndrome in infants born to susceptible mothers who were inadvertently immunized.[21]

Inactivated vaccines do not appear to pose a risk to the fetus and may be safely administered where indicated in the second or third trimester. Inactivated influenza vaccine is recommended for all pregnant women during any trimester.

Specific Immunization Guidelines For Healthcare Personnel

HEPATITIS A

Vaccine Type

There are currently three vaccines containing Hepatitis A virus (HAV) antigen currently licensed in the United States for adults. There are two single-antigen vaccines: HAVRIX (GlaxoSmithKline [SKB], Brentford, UK) and VAQTA (Merck, Whitehouse Station, NJ); and a combination vaccine TWINRIX (containing both HAV and Hepatitis B virus [HBV] antigens; GlaxoSmithKline). All are inactivated vaccines.[22]

Indications

HCP have not been demonstrated to be at increased risk for HAV infection because of occupational exposure, including persons exposed to sewage. Hepatitis A vaccine is recommended for persons with chronic liver disease, international travelers, and certain other groups at increased risk for exposure to Hepatitis A. For adults, the most recent guidelines from ACIP recommend the Hepatitis A vaccine for pre-exposure prophylaxis against HAV in those individuals at increased risk for infection and for anyone wishing to obtain immunity against this infection.[22]HCP should receive the Hepatitis A vaccine if they fall into a group at increased risk of infection, work in an area with occupational risk of infection, or if they wish to be immune to HAV infection. The two situations with occupational risk are persons who work with HAV-infected primates or those who work with HAV in a research laboratory setting. HCP at increased risk or who wish to be immune to this infection should inquire about receiving this vaccine from their private healthcare provider (if their place of employment does not provide this vaccine).

Individuals/groups that are or will be at increased risk for HAV infection, and for whom Hepatitis A vaccine is recommended, include:

- Travelers to or persons working in countries with intermediate to high endemicity of HAV infection (including military personnel)
- Men who have sex with men
- Users of injection and noninjection illicit drugs
- HCP who work with HAV-infected primates or with HAV in a research laboratory setting (or other persons with occupational risk of infection)
- Persons who are administered clotting factor concentrates (especially solvent-detergent treated preparations) for clotting factor disorders
- Persons with chronic liver disease, persons waiting or having received liver transplants (not persons with chronic HBV or Hepatitis C virus [HCV] infections without evidence of liver disease)

ACIP's updated statement does not include routine indications for prisoners, staff, and residents of facilities for the developmentally disabled, employees in child day care centers, food handlers, or sewage workers. Hepatitis A vaccination of food handlers might be considered for those who work in areas determined by state and local health authorities or private employers to be appropriate.[21]

Side Effects

All studies to date indicate the exceptional safety profile of the Hepatitis A vaccines. In studies to date, side effects reported in up to 50 percent of recipients included pain and tenderness at the injection site, headache, diarrhea, and other nonspecific symptoms of approximately equal frequency to placebo.[23]In a study of 151 HCP, the most frequent reported side effect was transient soreness at the site of injection in 27 percent of recipients, with no major symptoms reported.[24]There is a single case report of

encephalopathy temporally associated with the third dose of the SKB vaccine in a single individual, with uneventful recovery after 48 hours.[25]

Slight, transient liver function abnormalities have occurred in some vaccine recipients. In one summary report of 104 studies utilizing the SKB vaccine involving >50,000 subjects and >120,000 doses of vaccine, a sero-conversion rate of 100 percent was observed with no serious adverse events considered related to vaccination. The most common adverse events reported to the Vaccine Adverse Events Reporting system from 1995 to 2005 included fever, injection site reactions, rash, and headache.[22]

Strategies for Administration

Mechanisms to ensure that two doses of vaccine are administered with appropriate spacing between doses are necessary. Computerized tracking databases are optimal, especially when used in conjunction with other HCP immunizations and health screening programs.

Spacing With Other Immunobiologics

The ability to initiate the Hepatitis A vaccine series while simultaneously providing immediate protection against infection for travelers by administering immunoglobulin (IG) is desirable. Studies to date generally indicate that IG can safely be administered simultaneously (different anatomical sites, separate injections) with the Hepatitis A vaccine, although the height of the antibody response may be slightly reduced.

Currently, it is recommended that IG continue to be given at the same time as the first dose of Hepatitis A vaccine for individuals who need immediate protection and who are expected to require the longer term protection necessary for pre-exposure prophylaxis, such as travelers to endemic areas. Future research may well indicate the efficacy of a single dose of vaccine as pre-exposure prophylaxis in adult travelers.

Use in Controlling Healthcare-Associated Transmission

Hepatitis A vaccine is not currently licensed for use as postexposure prophylaxis (PEP). There are limited data regarding its efficacy when used during community-wide outbreaks of Hepatitis A, outbreaks in child day care centers, or in foodborne illness outbreaks.[22]

However, IG both prevents and modifies HAV infection and hence is appropriate for prophylaxis in travelers and as PEP in those exposed by close, personal household or sexual contact with a case, or in association with a known outbreak of HAV. IG is a sterile preparation of concentrated antibodies (immunoglobulin) made from pooled human plasma by a process called cold ethanol fractionation. IG provides protection against HAV through passive transfer of antibody.

For PEP and short-term travel (less than 3 months) a single dose of IG (0.02 mL/kg, up to 2 mL) should be given intramuscularly (IM) as soon as possible after exposure or prior to travel. Administration more than 14 days after an exposure is unlikely to be beneficial and hence is not indicated. IG is not recommended for casual contacts of persons with HAV.

For long-term travel, the dose of IG used is 0.06 mL/kg, up to 5 mL IM. The dose should be repeated every 4 to 6 months for the duration of the period at risk.

Contraindications

The currently licensed Hepatitis A vaccine is an inactivated vaccine and cannot cause Hepatitis A. Hepatitis A vaccine should not be administered to persons with a history of a severe allergic reaction to a previous dose of Hepatitis A vaccine or to a vaccine component. There are no other known contraindications other than hypersensitivity.

The safety of Hepatitis A vaccination during pregnancy has not been determined; however, because Hepatitis A vaccine is produced from inactivated HAV, the theoretical risk to the developing fetus is expected to be low. The risk associated with vaccination should be weighed against the risk for Hepatitis A in pregnant women who might be at high risk for exposure to HAV. Because Hepatitis A vaccine is inactivated, no special precautions need to be taken when vaccinating immunocompromised persons.[22]

Administration Schedule

The Hepatitis A vaccine should be administered IM into the deltoid muscle, using a length appropriate for the person's age and size.

The adult formulations of VAQTA and HAVRIX are administered in a two-dose schedule (VAQTA: at time 0, 6 to 18 months later; HAVRIX at time 0, 6 to 12 months later). Primary immunization with TWINRIX consists of three doses, administered on a 0-, 1-, and 6-month schedule, the same schedule as that commonly used for single-antigen Hepatitis B vaccine.[26]See Table 103-6 for dosages.

Table 103-6.Dosage Schedule for Hepatitis A and Hepatitis A and B Vaccines[22]

Table 103-6 Dosage Schedule for Hepatitis A and Hepatitis A and B Vaccines

Age of Vaccinee (years)	Dose	Volume (mL)	Number of Doses	Schedule (months)
HAVRIX				
1–18	720	0.5	2	0, 6 to 12
>18	1,440	1.0	2	0, 6 to 12
VAQTA				
1–18	25	0.5	2	0, 6 to 18
>19	50	1.0	2	0, 6 to 18
TWINRIX				
>18	720	1.0	3	0, 1, 6

For HAVRIX and TWINRIX, the antigen content of the final aqueous preparation is determined by reactivity in a quantitative immunoassay for HAV antigen, and final vaccine potency (per dose) is expressed as enzyme-linked immunosorbent assay (ELISA) units (EL.U.). For VAQTA, the antigen content is expressed as units (U) of HAV antigen.[22]

Post Vaccination Serological Testing

This is not indicated because of the high rate of vaccine response among adults and children.

Effectiveness and Safety

All studies to date indicate that these vaccines are highly immunogenic with excellent safety profiles.[23]

After a single dose of either vaccine, seroconversion rates >90 percent are routinely observed, with HAV antibody (anti-HAV) levels approximating those achieved by a 5-mL dose of IG.[23]

Specifically, after a single 1,440 EL.U. dose of vaccine in adults, 80 to 90 percent have protective levels of antibody after 15 days, and >96 percent seroconvert after 30 days. When a booster dose is given 6 months later, essentially 100 percent of recipients seroconvert. Protective antibody titers develop within 15 to 30 days after vaccination.

After three doses of TWINRIX, antibody responses to both antigens are equivalent to responses seen after the single antigen vaccines are administered separately on standard schedules.

Unresolved Issues

Further studies are needed on the duration of clinical protection after immunization with Hepatitis A vaccine and the need for possible booster doses.

Current data show that protective antibody levels achieved after immunization persist for 5 to 10 years, and preliminary data suggest protective antibody levels may persist for 16 to 25 years;[27]however, the duration of immunologic memory likely may even exceed this time frame.

Recommendations regarding the need for prevaccination serology testing have been evolving. Data from the NHANES III study conducted from 1988 to 1994 showed a prevalence of anti-HAV in a random sample of the general U.S. population of 31 percent.[28]In this study, anti-HAV prevalence increased with age, from 9 percent in children age 6 to 11 years, to 33 percent in adults 40 to 49 years, and to 74 percent in adults more than 50 years. Decisions to perform prevaccination serology testing before administering Hepatitis A vaccine should be based on the expected prevalence of immunity, the cost of vaccination versus testing, and whether such testing will interfere with initiation of vaccination. ACIP has suggested prevaccination testing of persons over the age of 40 before administering Hepatitis A vaccine. Other adults that might be considered for prevaccination serology testing include those born in or living for extensive periods in areas with high or immediate Hepatitis A endemicity, those in certain population groups (Native Americans, Alaska Natives, Hispanics), and those in groups with high prevalence of infection (e.g., injection drug users).[22]Further cost-benefit analyses are needed to determine the role of prevaccination antibody screening in various epidemiologically defined groups.

Although preliminary data suggest that vaccine alone may be useful as PEP and in controlling outbreaks, ACIP recommends studies be completed comparing IG with Hepatitis A vaccine before the vaccine can be recommended for PEP.[22]

Future studies may indicate the efficacy of a single dose of vaccine alone as preexposure prophylaxis for travelers who receive the vaccine at least 14 days prior to travel.

Lastly, accelerated short-term immunization schedules are being investigated.

Commonly Asked Questions

- Can a single dose of the vaccine be used as immediate PEP? The answer to this is unclear, and further studies are needed. Preliminary data suggest that the vaccine alone may be useful as PEP

and in controlling outbreaks.[27]However, more data are needed to be conclusive on this issue.

- Can you get hepatitis from the vaccine? Is it a live viral vaccine? You cannot get hepatitis from the vaccine. The vaccine is a whole virus, but an inactivated vaccine. The vaccine-manufacturing process inactivates all known viruses.
- Can you give Hepatitis A vaccine in combination with immunoglobulin? Is it still effective? Yes, both can be given together. Doses of IG of 2 mL or less do not appear to interfere with antibody production. Doses of 5 mL appear to decrease peak antibody titers.
- Should you test for antibody after receiving the vaccine to ensure immunity? There is no current recommendation for post-immunization serological testing. As a practical matter, the vaccine is very highly immunogenic, and in clinical trials essentially all subjects seroconverted after two doses of vaccine.
- Can you receive Hepatitis A and B vaccines at the same time? Absolutely yes! The vaccines should be given with different syringes and at different anatomical sites. Alternatively, there is a combination Hepatitis A and B vaccine available.
- Is a single dose of vaccine sufficient to confer protection? In young healthy adults, 80 to 90 percent have protective levels of antibody 15 days after receiving the first dose of vaccine, and 96 percent seroconvert after 30 days. The booster dose given 6 months later leads to essentially 100 percent seroconversion. Whether this will be true when widely applied to the entire general population is unclear.

HEPATITIS B

Vaccine Type

There are currently three Hepatitis B vaccines licensed for adults in the United States: two single-antigen and one combination formulation. The two single-antigen formulations are Recombivax HB (Merck) and Engerix-B (GlaxoSmithKline Biologicals). The combination vaccine is TWINRIX (GlaxoSmithKline).[27,29,30]

The antigen used for Hepatitis B vaccination is Hepatitis B surface antigen (HBsAg), which is either purified from the plasma of persons with chronic HBV infection or produced by recombinant DNA technology. In the United States, recombinant DNA technology is used to express HBsAg in yeast, which then is purified. The two single-antigen vaccines available in the United States are recombinant subunit vaccines. TWINRIX contains recombinant HBsAg and inactivated HAV. The plasma-derived vaccine is no longer available in the United States, but is available in other parts of the world.[27]

Indications

In adults, Hepatitis B vaccine is recommended for pre- and postexposure prophylaxis for all persons at risk for infection by percutaneous or mucosal exposure to blood, sexual exposure, international travel, presence of certain medical conditions, and anyone seeking protection from HBV infection. HCP and public safety workers with reasonably anticipated risk for exposure to blood or blood-contaminated body fluids should receive the vaccine.

The following settings have been identified as those in which Hepatitis B vaccination is recommended for all adults:

- Sexually transmitted infection treatment facilities

- HIV testing and treatment facilities
- Facilities providing drug abuse treatment/prevention services
- Healthcare settings targeting services to injection drug users or men who have sex with men
- Correctional facilities
- End-stage renal disease programs and facilities for chronic hemodialysis patients
- Institutions and nonresidential day care facilities for persons with developmental disabilities[27,28,29]

Thus, HCP in these settings should be vaccinated.

Serological screening is not necessary prior to immunization unless the institution considers it cost effective or the HCP specifically requests it. There are no known adverse effects to immunizing someone who may already be immune because of previous infection or immunization.

Side Effects

- Mild soreness at the injection site lasting up to 1 to 2 days can occur in up to 29 percent of recipients.
- Occasionally nonspecific constitutional symptoms (low-grade fever [1 to 6 percent], myalgias, malaise, etc.) occur.
- Rare incidence of severe adverse experiences.

Strategies for Administration

Ideally, immunization against HBV should be completed during health professional training because the risk for infection is thought to be highest at this time.[27,29,30] All HCP should be offered vaccine at the time of employment.

Spacing with Other Immunobiologics

Hepatitis B vaccine can be given at any time, in conjunction with any other vaccines, although at different anatomical sites and using separate syringes.

Use in Controlling Healthcare-Associated Transmission

Immunizing HCP against HBV prevents healthcare-associated transmission of the virus from HCP to patient, and from patient to HCP.[27,29,30] PEP after exposure to blood or body fluids is outlined in Table 103-7.

Table 103-7.Postexposure Prophylaxis for Hepatitis B in HCP[27]

Table 103-7 Postexposure Prophylaxis for Hepatitis B in HCP

Vaccination and Antibody Status of Exposed Workers*	Treatment	
Source HBsAg† Positive	Source HBsAg† Negative	Source Unknown or Not Available for Testing

Unvaccinated	HBIG§ X 1 and initiate HB vaccine series¶	Initiate HB vaccine series	Initiate HB vaccine series
Previously vaccinated	No treatment	No treatment	No treatment
Known responder**	HBIG X 1 and initiate revaccination or HBIG X 2§§	No treatment	If known high risk source, treat as if source were HBsAg positive
Known non responder††		No treatment	
Antibody response unknown	Test exposed person for anti-HBs 1. If adequate,** no treatment is necessary 2. If inadequate,†† administer HBIG X 1 and vaccine booster		Test exposed person for anti-HBs 1. If adequate,¶ no treatment is necessary 2. If inadequate,¶ administer vaccine booster and recheck titer in 1–2 months

*Persons who have previously been infected with HBV are immune to reinfection and do not require postexposure prophylaxis.

†Hepatitis B surface antigen.

§Hepatitis B immunoglobulin; dose is 0.06 mL/kg intramuscularly.

¶Hepatitis B vaccine.

**A responder is a person with adequate levels of serum antibody to HBsAg (i.e., anti-HBs ≥10 mIU/mL).

‡A non responder is a person with inadequate response to vaccination (i.e., serum anti-HBs <10 mIU/mL).

§§The option of giving one dose of HBIG and reinitiating the vaccine series is preferred for nonresponders who have not completed a second three-dose vaccine series. For persons who previously completed a second vaccine series but failed to respond, two doses of HBIG are preferred.

¶¶Antibody to HBsAg.

From Centers for Disease Control and Prevention. Updated U.S.P.H.S. guidelines for the management of occupational exposures to HBV, HCV, and HIV and recommendations for post exposure prophylaxis. *MMWR Recomm Rep*2001;50(RR11):1–42 (Table 3).

Contraindications

Hepatitis B vaccination is contraindicated for persons with a history of hypersensitivity to yeast or any vaccine component.

Persons with a history of serious adverse events (e.g., anaphylaxis) after receipt of Hepatitis B vaccine should not receive additional doses. As with other vaccines, vaccination of persons with moderate or severe acute illness, with or without fever, should be deferred until illness resolves.

Vaccination is not contraindicated in persons with a history of multiple sclerosis, GBS, autoimmune disease (e.g., systemic lupus erythematosus or rheumatoid arthritis), or other chronic diseases.

Pregnancy is not a contraindication to vaccination. Limited data suggest that developing fetuses are not at risk for adverse events when Hepatitis B vaccine is administered to pregnant women. Available vaccines contain noninfectious HBsAg and should cause no risk of infection to the fetus.[27,29,30]

Administration Schedule

- Immunization against HBV requires three doses, administered IM in the deltoid muscle, regardless of the formulation.
- Adults should receive one 1-mL dose initially, which is repeated at 1 and 6 months.
- The vaccine concentrations as currently formulated are 20 µg/mL for Engerix-B, 10 µg/mL for Recombivax HB, and TWINRIX contains 720 EL.U. of Hepatitis A antigen (50 percent of the HAVRIX adult dose) and 20 µg of recombinant HBsAg protein (the same as the ENGERIX-B adult dose). Higher doses (40 µg/mL) are recommended to provide protection for dialysis and immunocompromised patients.[27,29,30]
- The SKB vaccine is also licensed for use on a 0-, 1-, 2-, and 12-month schedule.
- A 1- or 1.5-inch needle should ensure that the vaccine is given IM, with longer needles necessary in obese persons.

Post Vaccination Serologic Testing

Routine serological testing in all recipients is not necessary after routine vaccination of adults. ACIP does advise serological testing for antibody 1 to 2 months after the last dose of the vaccine in persons whose "subsequent clinical management depends on knowledge of their immune status . . . to determine the need for revaccination and to guide post-exposure prophylaxis."[31]This includes the following groups: certain HCP and public safety workers who are at high risk of continued percutaneous/mucosal blood/body fluid exposure; chronic hemodialysis, HIV-infected, and other immunocompromised individuals; and sex- or needle-sharing partners of HBsAg-positive persons. Examples of HCP and public safety workers at high risk include the following:

- Acupuncturists
- Dentists, dental hygienists
- Emergency medical technicians
- First responders
- Laboratory technologists/technicians
- Nurses, nurse practitioners
- Phlebotomists
- Physicians
- Physician assistants
- Students entering these professions[27,29,30]

Booster doses are not routinely recommended.

An algorithm has been published dealing with the issues on nonresponse to Hepatitis B vaccine in HCP, with guidelines as to how and when to test for Hepatitis B antibody and what dose(s) of Hepatitis B vaccine to administer, based on risk factors.[32]

Effectiveness and Safety

When properly administered, the three-dose series induces seroconversion in more than 90 percent of otherwise healthy young adults. However, vaccine immunogenicity is related to several factors, such as concomitant medical conditions, gender, age, body weight, and smoking status.

Persons who initially respond to the vaccine with an appropriate antibody response, but who later have waning antibody levels appear to be protected. Hepatitis B surface antibody (anti-HBs) levels decline over time. Regardless, responders continue to be protected, and the majority of responders will show an anamnestic response to vaccine challenge. Declines might be faster among persons vaccinated at a younger age. Persons who do not have protective levels of anti-HBs 1 to 2 months after revaccination with a second series should be considered nonresponders. Genetic factors may be associated with nonresponses to Hepatitis B vaccination. ACIP does not recommend more than two vaccine series in nonresponders.

Unresolved Issues

- Duration of vaccine-induced protection
- Management of vaccine nonresponders
- Need and frequency for post-vaccination antibody screening and/or routine booster doses of vaccine in the general population

Commonly Asked Questions

- How close does the actual vaccine administration schedule have to be to the recommended schedule for the vaccine to be effective? In general, optimal antibody titers are produced by an interval of at least 1 month between the first two doses and at least 5 months between the second and third doses. The longer the time interval between the second and third doses, the better the antibody response in general, but with the trade off that some individuals will not be protected until receipt of the third dose of vaccine. Thus, the greatest danger comes in trying to decrease the time interval between doses. No matter when previous doses were given, it is safe and effective to simply resume the immunization schedule where it was left off.
- What happens if the vaccine freezes? Freezing destroys the potency of the vaccine, and the vaccine should be discarded. The vaccine should be stored at 2° to 6°C.
- If anti-HBs antibody titers are going to be checked, when is the best time to do so? Anti-HBs titers should be checked no sooner than 30 days after the last dose of vaccine and no later than 6 months after the last dose. The optimal time to determine vaccine response is probably 1 to 2 months after the last dose of vaccine.
- Should we be performing post-immunization antibody testing in HCP? The current recommendations are for post-immunization antibody testing only in persons whose “subsequent clinical management depends on knowledge of their immune status . . . to determine the need for revaccination and to guide post exposure prophylaxis.”[27]For the most part, this includes most HCP.
- What options do you have with nonresponders? First it is important to determine if the individual is truly a nonresponder. Negative or low antibody determinations performed more than 6 months after

the last dose of vaccine only tell you that the subject could be a normal responder with waning antibody titers, a hyporesponder, or a true nonresponder. An algorithm has been published outlining and detailing the options for trying to correct nonresponse.[32]

- Nonresponders are defined as those individuals who have received the appropriate vaccine dose in an appropriate dosing interval, in the deltoid muscle, and have no antibody response (less than 10 mIU/L) where the anti-HBs antibody was determined in the 1- to 6-month window after the third dose of vaccine.
- Nonresponders can receive another dose of vaccine (with an estimated 20 percent response rate) or another series of three doses (with an estimated 30 to 50 percent response rate). Individuals not responding after a total of six doses of vaccine are unlikely to respond to further vaccine doses.
- If it is thought that the "nonresponse" is actually a case of waning immunity, a single dose of vaccine is administered with a 1- to 1.5-inch needle to the hub and the anti-HBs determined 1 month later. If this is negative, then another two doses are administered according to the usual schedule, with an anti-HBs determined 1 month after the third dose.
- If the negative anti-HBs titer is thought to be true nonresponse, then a new series of three doses of vaccine are administered according to the usual schedule, but the 40 mcg "dialysis preparation" dose is used for greater immunogenicity. The vaccine is administered with a 1- to 1.5-inch needle inserted into the deltoid muscle to the hub of the syringe, with the needle held parallel to the ground.[33]

- What should you do for those persons with waning immunity? This refers to those who previously received the Hepatitis B series and were antibody (anti-HBs) positive, but at a later date were found to be antibody negative. Studies show a very low rate of asymptomatic seroconversion among such persons who are subsequently exposed to Hepatitis B, with no evidence of chronic carriage of the virus. This is felt to result from the protective effects of immunological memory. Hence, nothing further needs be done.
- Can the vaccine be administered intradermally (ID)? The vaccine has been used this way in several studies. Although this saves money on vaccine costs, it introduces several concerns. First, the vaccine is not licensed for ID administration. Second, ID administration can result in a lower frequency of protective levels of antibody. Third, post-immunization antibody response should be determined in all recipients of ID administered vaccine, which defeats the purpose of giving the vaccine by this route to lower costs. Lastly, ID administration has been reported to produce pigmented papules, which may be cosmetically undesirable.
- Why can't the vaccine be given by gluteal injection? The vaccine is no longer licensed for gluteal administration because of the high incidence of nonresponse. This is thought to relate to the likelihood that vaccine could be administered into the gluteal fat pad (rather than muscle), thus decreasing vaccine immunogenicity.[34]

- Are regular booster doses of Hepatitis B vaccine advisable? At present, there are no recommendations for booster doses in otherwise healthy individuals. HCP who plan on working in hyperendemic geographic areas (e.g., medical missions in developing world countries) might wish to determine their anti-HBs titer and re-immunize if seronegative. Other than cost, there is no known adverse effect to immunizing an immune individual.

INFLUENZA

Vaccine Type

Several different preparations of influenza vaccine are available. These include inactivated split virus and live attenuated preparations. Every year the specific strains and number of viruses vary and are determined by the World Health Organization in collaboration with other organizations. The U.S. Food and Drug Administration (FDA) then recommends which strains will be used in the Unted States.

Each vaccine normally contains three or four strains of influenza: two type A strains and one or two type B strains. New vaccines are made every year because the strains causing disease change yearly.

Indications

Annual influenza vaccination is recommended for all persons aged >6 months who have no medical contraindications; therefore, vaccination of all HCP who have no contraindications is recommended. HCP are exposed to patients with influenza in the workplace and are thus at risk of occupationally acquired influenza and of transmitting influenza to patients and other HCP.[11]

Live attenuated influenza virus (LAIV) is administered intranasally and is licensed for healthy, nonpregnant persons aged 2 to 49 years. It should not be administered to persons who are immunocompromised or who have serious health conditions. LAIV may cause nasal congestion or runny nose, sore throat, headache, and cough in adults. Fever is not a common side effect of LAIV.[35,36]

Side Effects

The vaccine cannot “cause” the flu. A randomized, double-blind, placebo-controlled, crossover trial showed no difference in side effects between vaccine and placebo recipients.[19]

Side effects of inactivated influenza vaccine (IIV) are generally minimal and minor, rarely lasting up to 24 hours, and include low-grade fever and injection site tenderness occurring in up to 20 percent of individuals.

Strategies for Administration

New polyvalent influenza virus vaccines are prepared every year, based on the anticipated infectious strains. One or more strains may be repeated in subsequent years, but re-immunization every year is recommended to achieve immunity.

Candidates should be vaccinated before the peak season for influenza infection, which usually begins in December. October is the optimal month to begin immunization programs, but vaccination can take place as early as September, provided that the most current vaccine is available, and continue as late as there are influenza outbreaks.

It takes about 14 days after immunization for protective levels of antibody to be produced and circulate in high enough titer to protect against disease.

Employee immunization programs that provide free vaccine in locations and at times that are convenient are likely to increase the number of HCP who receive the vaccine, although high, sustainable rates have not been demonstrated without a mandatory policy. Influenza vaccination rates among HCP within facilities should be regularly measured and reported. Influenza vaccination coverage among HCP should be a measure of quality of care. Such information might be useful to promote compliance with vaccination policies.

One study demonstrated that healthy working adults who received influenza vaccine experienced significantly fewer upper respiratory infections, fewer days of sick leave from work, and less health-related direct costs.[7]

Spacing with Other Immunobiologics

The inactivated vaccine can be given concomitantly with any other vaccine, although at different anatomical sites and using different syringes. The most current ACIP recommendations state that LAIV can be administered simultaneously with inactivated or live vaccines. However, if LAIV and another live vaccine are not given concurrently, at least 4 weeks should elapse before another live vaccine is administered.

Use in Controlling Healthcare-Associated Transmission

Influenza vaccines are effective in preventing healthcare-associated transmission of influenza. For this reason, all HCP caring for hospitalized and other high-risk subjects should receive influenza vaccine on an annual basis.

Centers for Medicare & Medicaid Services (CMS) recommends as part of their conditions of participation that a policy is in effect whereby nursing annually (October 1 to March 30) reviews the indications and contraindications for influenza vaccine for every hospitalized patient. If appropriate, patients are immunized prior to hospital discharge.[37]

Descriptions of programs to immunize high-risk hospitalized patients and outpatients are available.[36]

Strategies to improve influenza vaccination rates have included sending postcards to patients to remind them to get the influenza vaccine and use of a drive-up immunization window for HCP.

Contraindications

Both Inactivated Vaccines and Live, Attenuated Influenza Vaccine

Influenza vaccine is produced using chicken eggs. Hence, persons with anaphylactic reactions to chicken eggs (not feathers!) or other components of the influenza vaccine should not receive this vaccine. Other allergic reactions to chicken egg proteins are also contraindications.

Persons who developed GBS or other neurological syndromes in temporal association (within 6 weeks) with receipt of influenza immunization should not receive further doses of vaccine. No cases of GBS have been reported because of LAIV.[35]

Additional Contraindications to Live, Attenuated Influenza Vaccine

In addition to the preceding contraindications, LAIV should not be administered to adults >49 years old, pregnant women, or persons at high risk for influenza complications with any of the underlying medical conditions that serve as an indication for routine influenza vaccination.

Administration Schedule

The dose of the IIV formulations is 0.5 mL administered IM (deltoid); LAIV is administered as an intranasal spray. Both are administered on an annual basis.

Post Vaccination Serological Testing

Not applicable.

Effectiveness and Safety

Influenza vaccines are safe and do not cause the flu. A randomized, double-blind, placebo-controlled, crossover trial demonstrated that side effects were no different among vaccine versus placebo recipients.[19]

The most common side effect of the inactivated vaccine is minor injection site soreness lasting 1 to 2 days. No known clinically significant changes in concomitantly administered drug pharmacokinetics occur (e.g., warfarin, theophylline, phenytoin). For LAIV, in adults, side effects have included runny nose, headache, sore throat, and cough.

The vaccine is highly effective in preventing clinical illness in young, healthy recipients.

Unresolved Issues

- Improved and more immunogenic/efficacious influenza vaccines are needed, especially for elderly and other high-risk persons.
- Methods to increase the number of HCP who receive annual influenza immunization are needed.
- Whether bias exists in estimating the benefits of vaccination among older adults and the relationship to hospitalizations and death
- Causality of rare events after influenza vaccination, such as GBS
- Expansion of routine influenza vaccination recommendations to reduce/prevent transmission and severe disease burden

Commonly Asked Questions

- Can the vaccine be administered intradermally or in “split” doses to try to reduce side effects? There is an intradermal flu vaccine that is injected into the skin instead of the muscle. The intradermal shot uses a much smaller needle than the regular flu shot, and it requires less antigen to be as effective as the regular flu shot. Antigen is the part of the vaccine that helps your body build up protection against flu viruses. Administering the IM vaccine in two split doses may significantly reduce the protective effect of the vaccine, with no evidence of a decrease in side effect rate or severity. LAIV should only be administered by the intranasal route.
- Can the vaccine be used in immunocompromised persons? Only the inactivated vaccine may be used —not the live, attenuated intranasal vaccine. Inactivated vaccine contains only inactivated virus, so there is no danger of viral replication. Although the vaccine may be less effective (depending on the degree of immune suppression) in such persons, it is particularly indicated in an effort to provide maximal protection against disease.
- Can the vaccine be used in HIV-positive persons? At the current time, the inactivated vaccine only is recommended for use in HIV-positive persons.[29’30’38]
- Can you get the flu from flu shots? This is a commonly expressed concern. Because inactivated vaccine contains only a killed virus, it is impossible to “get the flu” from this vaccine. A recent study

showed that flulike symptoms were equally common among flu vaccine and placebo recipients.[28]

However, reported side effects from the LAIV have included transient upper airway symptoms such as runny nose, sore throat, and minor systemic symptoms such as myalgias and low-grade fever.[35]

- What about the risk of GBS after getting the flu vaccine? There have been no confirmed cases of GBS caused by inactivated influenza vaccine since the period 1976 to 1977, when the “swine flu” vaccine was used. Little direct evidence exists of any cause-and-effect association of flu vaccine with GBS since then. No cases of GBS have been reported because of LAIV.
- Can patients with a previous history of GBS or other demyelinating disorders safely receive the flu shot? It is prudent to delay immunizing anyone with an active neurological disorder characterized by changing or unstable neurological findings. ACIP and American College of Physicians (ACP) recommendations are that flu vaccine not be given to individuals who have had GBS or other neurological illnesses temporally related (i.e., within 6 weeks) to previously administered vaccine.
- Can I get other vaccines at the same time as the IIV? Among adults aged ≥50 years, the safety and immunogenicity of zoster vaccine and IIV were similar whether administered simultaneously or spaced 4 weeks apart. In the absence of specific data indicating interference, following ACIP’s general recommendations for vaccination is prudent.[8]All other adult vaccines can be given at the same time

  as the inactivated influenza vaccines, but at different anatomical sites. Inactivated vaccines do not interfere with the immune response to other inactivated vaccines or live vaccines.
- Can the nasal spray vaccine (LAIV) be given at the same time as other vaccines? Use of LAIV concurrently with MMR alone, and MMR and varicella vaccine among children aged 12 to 15 months has been studied, and no interference with the immunogenicity to antigens in any of the vaccines was observed. In the absence of specific data indicating interference, following ACIP’s general recommendations for vaccination is prudent.[8]Inactivated or live vaccines can be administered

  simultaneously with LAIV. However, after administration of a live vaccine, at least 4 weeks should pass before another live vaccine is administered.
- Are there any medications that can’t be taken at the time of the flu shot? There are no medications that are contraindications to receiving the flu vaccine. However, corticosteroids, chemotherapy agents, and other immune suppressives may decrease the ability of the immune system to respond to the vaccine with protective levels of antibody.
- What are true contraindications to receiving influenza immunization? Anyone with a previous anaphylactic, bronchospastic, or hypotensive reaction to flu vaccine should not receive additional doses of flu vaccine. Additionally, anaphylactic reactions to eggs, egg proteins, or any component of the vaccine or thimerosal (a mercury-derived preservative) are true contraindications. LAIV should not be administered to anyone other than healthy persons aged 2 to 49 years who are not pregnant and who have no chronic or serious medical conditions. It is currently licensed for use only in healthy individuals. Use of LAIV for HCP who care for patients housed in protective environments has been a theoretic concern, but transmission of LAIV in healthcare settings has not been reported.
- Can patients on warfarin or heparin receive flu shots? Taking warfarin or heparin is not a contraindication. It is medically prudent to delay immunizing someone with an uncontrolled bleeding disorder/coagulopathy until the condition is stable.
- Many employees delay the flu vaccine because they are sick. What is the danger of receiving this vaccine when you are under the weather? There is no danger to receiving the flu vaccine during a mild illness. It is prudent to delay receiving the vaccine with a more severe illness/fever simply to avoid labeling a changing clinical course as an adverse reaction to the flu vaccine.

MEASLES-MUMPS-RUBELLA

Vaccine Type

Measles, mumps, and rubella vaccines are all live, attenuated viral vaccines. The vaccines are available as monovalent, bivalent, and trivalent vaccines. There is also a combination vaccine of MMR with varicella (Pro-Quad [Merck], but that is not indicated in adults). Currently licensed vaccines for adults in the United States are all manufactured by Merck & Co. and include:

- Monovalent (measles only, Attenuvax; mumps only, Mumpsvax; and rubella only, Meruvax)
- Bivalent (measles and mumps, M-M-vax, although currently not available)
- Trivalent (measles, mumps, and rubella, M-M-R II)

Indications

Medical staff and hospital employees are at increased risk of acquiring measles, mumps, and rubella.[2,3,39]

- All persons working in healthcare facilities should be immune to measles, mumps, and rubella.[5] Additionally, it is reasonable to require proof of immunity in the medical setting.
- HCP proof of immunity consists of documented vaccination with two doses of live vaccine administered at least 28 days apart, laboratory evidence of immunity to these diseases, or laboratory confirmation of disease. If such proof is not available, immunization with MMR provides long-lasting protection against all three diseases and is not harmful to persons already immune against one or more of its components. The exception is a medical contraindication to the vaccine.[30]
- Even though persons born before 1957 usually have acquired immunity against measles and rubella as a result of wild virus exposure, healthcare facilities should consider recommending a dose of MMR vaccine to unvaccinated workers born before 1957 who are in either of the following categories: (1) do not have a history of measles disease or laboratory evidence of measles immunity, or (2) lack laboratory evidence of rubella immunity.[30]
- For HCP born in 1957 or later, give two doses of MMR 4 weeks apart if they do not have proof of immunity.[30]

For HCP who have two documented doses of MMR vaccine or other acceptable evidence of immunity to measles, serologic testing for immunity is not recommended. In the event that the HCP has two documented doses of MMR vaccine and tests serologically negative or equivocal in titer results, it is not recommended that the person receive an additional dose of MMR vaccine.

- The dose of MMR or any of the monovalent component vaccines is 0.5 mL administered subcutaneously.
- All HCP at risk of contact with patients with rubella or who are likely to have direct contact with pregnant patients should be immune to rubella.
- Prior to immunization, serological screening is not necessary unless the institution considers it cost effective or the HCP specifically requests it.
- As with measles, mumps, and rubella, immunization is not harmful for persons already immune, and consideration should be given to the use of trivalent MMR, rather than monovalent vaccine.

Side Effects

- Fever may result after vaccination; the measles component of MMR is most often associated with this adverse event.
- Transient vaccine-associated rashes occur in up to 5 percent of recipients.
- Both parotitis and central nervous involvement have rarely been reported after mumps immunization.
- As many as 25 percent of susceptible women may experience transient arthralgias or arthritis after rubella immunization. When these side effects occur, they generally occur 1 to 3 weeks after immunization and resolve within days to weeks.
- Short-lived peripheral neuritis and paresthesias have been rarely reported in association with rubella immunization of nonimmune individuals.

Strategies for Administration

- MMR is the preferred vaccine formulation. Immunization with MMR is not harmful to a recipient already immune to one or more of these viruses.
- Without proof of immunity, all HCP should ideally receive two doses of MMR, spread apart by a minimum of 1 month between doses.

Spacing with Other Immunobiologics

- Administration of measles vaccine causes temporary mild immune suppression. Under routine use of the licensed vaccine, the only clinical significance of this effect is false-positive tuberculin skin test (TST) after immunization. Measles-containing vaccine can be administered on the same day as TST. If it cannot, then more than 4 weeks should elapse after MMR vaccination to perform TST.[8]
- The vaccine should be given 2 weeks before gammaglobulin or other blood products, or up to 11 months after receipt (depending on the dose of blood product received), for optimal immunogenicity.[18]
- Co-administration with other live viral vaccines (other than oral polio vaccine or varicella) should be avoided and separated by at least 30 days.

Use in Controlling Healthcare-Associated Transmission

- *The Redbook*recommends measles immunization for those individuals who may not be protected and were exposed to measles within a 72-hour time frame. Nonetheless, these individuals must be relieved of patient duties from days 5 to 21 after exposure.

Contraindications[18]

- Pregnant women or women anticipating conception in the 4 weeks after immunization.
- Previous severe hypersensitivity reaction (including anaphylaxis) to the vaccine or any of its components.
- Known severe immune deficiency (e.g., hematological and solid tumors; receiving chemotherapy; congenital immune deficiency; long-term immune suppressive therapy; or patients with HIV infection who are severely immunocompromised). The one exception is that HIV-positive persons may receive the vaccine if they are: (1) asymptomatic, (2) have an age-specific CD4+ T-lymphocyte percentage of >15 percent, and (3) are one of those persons for whom measles vaccination would otherwise be indicated.

- Precautions include moderate or severe illness with or without fever, history of thrombocytopenia or thrombocytopenic purpura, and recent (<11 month) receipt of antibody-containing blood product (interval depends on specific product).[18]

Administration Schedule

- A second dose of vaccine should be given and documented for all HCP born after 1957 and for those born before 1957 without adequate evidence of immunity.
- Immunization is not necessary for those with documented immunity by serology or by provider-diagnosed illness.
- The vaccine must be used within 8 hours of vaccine reconstitution.

Post Vaccination Serological Testing

Not usually done. Testing for MMR antibody can be done to document immunity in HCP who do not wish to receive a second dose of vaccine.

Effectiveness and Safety

These vaccines are safe and efficacious. Failure rates are in the 5 percent or less range. Seronegative recipients of rubella vaccine, especially adolescent and adult women, appear to have an increased risk of arthralgias and arthritis. The risk appears to be small, and is generally short lived. Occasionally, chronic arthritis has been reported. Rare, isolated cases of polyneuropathy have been reported after immunization with this vaccine or its components.

Rare cases of optic neuritis, viral meningitis, parotitis, and orchitis have been reported following mumps immunization.

Unresolved Issues

- The risk, duration, and pathogenesis of arthritis owing to rubella immunization in seronegative adolescent and adult women need further clarification.
- The impact of waning immunity, especially for measles and mumps, needs additional study.

Commonly Asked Questions

- Should the monovalent measles vaccine be given alone or in combination with the MMR vaccine? Unless there is some other contraindication, it is advisable to receive the protective effect of all three vaccines. There is no harm in immunizing an otherwise immune individual. The known arthralgia and arthritis side effects of rubella vaccine that can occur in seronegative persons do not occur in those who receive the vaccine but are already immune.
- Why is a history of recent receipt of blood products important to know prior to immunizing someone with MMR vaccine? The IG present in these products can interfere with optimal antibody production to the vaccine. Large doses of IG can interfere with vaccine immunogenicity for as long as 9 to 12 months.
- Why don't all HCP receive a dose of measles vaccine, rather than just those born after 1957? Persons born prior to 1957 are statistically more likely to have had wild virus infection, and hence be immune. Nonetheless, several surveys of HCP born prior to 1957 have demonstrated up to a 14 percent seronegative rate. An expert consensus report was published outlining the optimal measles immunization strategy for HCP.[40]In this report the optimal strategy proposed was for all HCP,

regardless of date of birth, to demonstrate immunity against measles. As a result, ACIP recommends that facilities consider recommending a dose of MMR to persons born before 1957 if there is no proof of immunity.[29]

- Is it safe to give MMR vaccine to HIV-positive persons? In the small number of persons studied, MMR vaccine has not caused unusual side effects in either symptomatic or asymptomatic individuals. Safety does not appear to be an issue in HIV-positive asymptomatic individuals. It is appropriate to assess the degree of immune suppression and the risk of measles exposure before administering measles vaccine to HIV-positive symptomatic persons. The most recent recommendation from ACIP is that measles vaccine not be administered to those HIV-infected persons who are severely immunocompromised (see Contraindications).[29]This recommendation is related to the death and subsequent finding of measles vaccine virus pneumonitis in an HIV-positive person.
- Because MMR is a live viral vaccine, can vaccinees transmit any of the three vaccine viruses to immunocompromised contacts? There is no evidence for transmission or any adverse effect from administering the vaccine to healthy persons who have contact with immunocompromised persons.

PNEUMOCOCCUS

Vaccine Type

Pneumococcal polysaccharide vaccine (PPSV) is a polyvalent vaccine that provides protection against the 23 types of pneumococci known to cause bacteremic disease. Pneumococcal conjugate vaccine (called PCV13 or Prevnar 13; Pfizer, New York, NY) is recommended to protect infants and toddlers, and some older children and adults with certain health conditions, from pneumococcal disease.

Indications

Although HCP are not at higher risk than the general adult population for acquiring pneumococcal disease, they may seek immunization because they fall into a high-risk category. The following conditions are indications for pneumococcal vaccine:

- Age 65 years or more.

PPSV is also recommended for persons <65 years with certain underlying medical conditions, including anatomic or functional asplenia; immunocompromise (including HIV infection); chronic lung, heart, or kidney disease; and diabetes.

Side Effects

- Local injection site soreness and erythema may occur in up to 50 percent of recipients, but usually subsides within 24 to 48 hours after administration.
- Anaphylactic reactions have occurred in persons receiving repeat doses of vaccine more often than the current recommendation repeat dosing 6 years after the first dose in high-risk individuals.
- Adverse effects on the fetus after vaccinating pregnant women have not been observed. The product insert advises administration to pregnant women only if clearly needed. It is prudent to wait until after the first trimester of pregnancy before immunizing.

Strategies for Administration

- The ACP's Task Force on Adult Immunization recommends that the 50th birthday be used as a date to review adult immunizations and determine specifically whether pneumococcal vaccine should be

given. After age 50, 30 to 40 percent of persons have a high-risk condition for which they should receive the vaccine.[29]The product insert for PPSV recommends routine vaccination of immune competent persons >50 years old.[41]

- Elderly persons with unknown vaccination status should receive one dose of the vaccine.
- There are no routine recommendations for revaccination following a second dose.[41]For revaccination schedule, see “Strategies for Administration.”
- It is recommended that the vaccine be administered at least 2 weeks before elective splenectomy if possible and at least 2 weeks prior to the initiation of immune suppressive therapy, as immune response to vaccination may be impaired.[41]
- Persons with asymptomatic or symptomatic HIV infection should be vaccinated as soon as their diagnosis is confirmed.[6]

Spacing with Other Immunobiologics

The vaccine can be administered at any time, concomitantly with other vaccines (including the influenza vaccination), but at different anatomic sites and using separate syringes. Intradermal administration may cause severe local reactions.[41]

Use in Controlling Healthcare-Associated Transmission

Not applicable.

Contraindications

- Hypersensitivity reaction to a previous dose of vaccine or any component of the vaccine.
- Revaccination is contraindicated for persons who had a severe reaction to the initial dose they received.
- Re-immunization more frequently than recommended increases the probability of Arthus-like reactions.
- Although there is no evidence that PPSV is harmful to either a pregnant woman or to her fetus, as a precaution, women with conditions that put them at risk for pneumococcal disease should be vaccinated before becoming pregnant, if possible.

Administration Schedule

The dose of this vaccine is 0.5 mL administered IM or subcutaneously (SQ), preferably in deltoid in adults.

Revaccination

Revaccination of immune competent persons previously vaccinated with one dose of PPSV is not routinely recommended.

ACIP has published guidelines and an algorithm for pneumococcal revaccination.[42]

For all other persons, only the following persons should receive a one-time revaccination:

- Persons age >65 who received the first dose prior to age 65 and 5 or more years have elapsed since that first dose

- Persons who are immunocompromised, have functional or anatomical asplenia, or have a condition that leads to rapid antibody loss (nephrotic syndrome, chronic renal failure, renal transplant) and 5 or more years have elapsed since the first dose

Post Vaccination Serological Testing

Not applicable.

Effectiveness and Safety

The vaccine is really 23 vaccines in one, with each serotype vaccine having its own failure rate. Although there has been controversy regarding the efficacy of the vaccine, numerous studies demonstrate that it effectively reduces the incidence of pneumococcal bacteremia among elderly high-risk persons. Recent case-control studies among elderly but otherwise healthy adults have shown efficacy rates of 50 to 70 percent.[41'42]

Studies of younger, healthy adults show excellent protective efficacy against pneumococcal pneumonia and bacteremia. Other than mild local reactions, the vaccine is safe. No neurological disorders have been causally linked to pneumococcal vaccine.

Prevnar 13, a pneumococcal 13-valent conjugate vaccine (which contains 13 different serotypes of the bacterium *Streptococcus pneumoniae*), was approved on December 30, 2011, by the FDA for adults aged 50 years and older to prevent pneumonia and invasive disease caused by the bacterium.

Unresolved Issues

- More immunogenic/efficacious vaccines are needed, and protein-conjugate vaccines are being developed.
- The optimal time for initial and re-immunization remains unclear.[42]

Commonly Asked Questions

- Can the vaccine be administered subcutaneously? The vaccine is licensed for either IM or SQ administration. It can cause severe allergic reactions if the vaccine is administered intradermally.
- Should the vaccine be given to adults younger than age 65 to improve the immunogenicity of the vaccine? ACP's Task Force on Adult Immunization recommends the 50th birthday as a time to assess the need for any immunizations, particularly the pneumococcal vaccine. If there are any indications (see previous discussion) for receiving the vaccine, it should be administered at this time.
- What should you do if you don't know whether pneumococcal vaccine was previously given? If a review of the medical records and inquiry to previous physicians attending the individual are unrewarding, it is reasonable to administer a dose of vaccine. Often a spouse can provide important information in this regard. This is consistent with the guidelines on pneumococcal immunization.[42]
- Can this vaccine be given at the same time as influenza vaccine? Absolutely yes! The vaccines should be given with different syringes at different anatomical sites.
- Who should be revaccinated? ACIP has published guidelines and an algorithm for pneumococcal revaccination.[42](See also Strategies for Administration in this section.)

POLIO

Vaccine Type

In the United States, only an enhanced-potency inactivated, parental whole virus vaccine (IPV) is available. Oral polio vaccine (OPV) has not been used in the United States since 2000 but is still used in many parts of the world. This U.S. policy was implemented to eliminate the risk for vaccine-associated paralytic poliomyelitis, a rare condition that has been associated with the use of the live OPV. The IPV vaccine currently licensed for use and distributed in the United States is IPOL (Sanofi Pasteur, Swiftwater, PA).[43,44]

Indications

Routine primary poliovirus vaccination of adults >18 residing in the United States is not recommended. Most have a minimal risk of poliovirus exposure in the United States and most are immune from childhood immunizations.

In adults, polio vaccine is indicated for those at increased risk of exposure to poliovirus as follows:

- Travelers to regions or countries where poliomyelitis is common
- HCPs in close contact with patients who could have polio
- Laboratory workers handling specimens that may contain polioviruses[43,44]

Side Effects: Enhanced-potency Inactivated Polio

No serious adverse effects have been documented because of this vaccine. However, you need to look for any unusual condition, such as a serious allergic reaction, high fever, or unusual behavior. If a serious allergic reaction occurs, it would happen within a few minutes to a few hours after the shot.

Spacing with Other Immunobiologics

Concomitant administration, of other parenteral vaccines, with separate syringes at separate sites, is not contraindicated. There are no known interactions of IPOL with drugs or foods.

Use in Controlling Nosocomial Transmission

HCP should be immune against polio. It is unlikely that HCP in the United States will come into contact with poliovirus.

Contraindications

- Persons with a history of severe allergic reaction (e.g., anaphylaxis) after a previous dose or to any component of the vaccine including antibiotics neomycin, streptomycin, or polymyxin B.
- Vaccination of persons with acute febrile illness should be deferred until after recovery.

Administration Schedule

- Enhanced-potency polio: four doses (0.5 mL SQ or IM in the deltoid) given at time 2 months, 4 months, 6 to 18 months, and a booster dose at 4 to 6 years.[44]
- For persons with increased risk of exposure who received an incomplete polio vaccine series, a total of four doses with inactivated vaccine is considered a complete series.
- Persons at increased risk of exposure to poliovirus who have previously completed a primary series with one or a combination of polio vaccines can be given additional doses of IPV. Those who have

had one or two doses of polio vaccine in the past should get the remaining one or two doses.

- Unvaccinated adults at high risk should receive the primary series of three doses. Two doses separated by 1 to 2 months, and a third dose 6 to 12 months after the second.[44]

Post Vaccination Serological Testing

Not applicable or usually done.

Effectiveness and Safety

- The vaccine is highly effective in preventing polio.
- After two doses of this vaccine, 98 to 100 percent seroconversion occurs.

Unresolved Issues

None.

Commonly Asked Questions

- Are HCP at risk for polio? Yes, although that risk may be low, the potential devastating effects of poliovirus infection are considerable. HCP may care either for patients from other parts of the world where polio is present or individuals who are excreting vaccine virus because of oral vaccine administration in other countries. HCP may travel to countries to work where polio is endemic. Finally, HCP who work in laboratories with poliovirus or polio vaccine viruses may be at risk of exposure.
- Is there a need for any type of booster dose of polio vaccine? Yes, adults who have had three doses of IPV or OPV but are at increased risk (e.g., travelers to endemic areas, HCP indications), can receive another dose of IPV. Otherwise, routine booster doses are neither necessary nor recommended.[43,44]

TETANUS-DIPHTHERIA-ACELLULAR PERTUSSIS

Vaccine Type

In the United States, there is currently one combination tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine, ADACEL (Sanofi Pasteur), licensed for use in adults. ADACEL contains a tetanus toxoid, a diphtheria toxoid, and acellular pertussis components. The vaccine also contains aluminum phosphate, residual glutaraldehyde, residual formaldehyde, and 2-phenoxyethanol. ADACEL does not contain thimerosal.[45,46]

Indications

HCPs are at risk of acquiring and transmitting pertussis, as evidenced by numerous reports of pertussis outbreaks and exposures in healthcare facilities. ACIP has published routine adult tetanus-diphtheria-acellular pertussis (Tdap) recommendations, as well as specific recommendations for HCP and pregnant/postpartum women.[46,47]

The following are recommendations for a single dose of Tdap. All adults 11 years and older, including those 65 years and older, should get a dose of Tdap vaccine.

- Routine recommendation: Adults should receive a single dose of Tdap to replace a single dose of tetanus-diphtheria (Td) for booster immunization against tetanus, diphtheria, and pertussis if they received the most recent tetanus-containing toxoid 10 or more years previously.
- Vaccination of HCP: Those who have direct contact with patients in hospitals and ambulatory care centers should receive a single dose of Tdap as soon as feasible if they have not previously received Tdap.
- Other HCP: Should receive a single dose of Tdap according to routine adult recommendations.
- For protection of infants aged <12 months: Adults (including parents, grandparents, or HCP) who have or anticipate close contact with an infant <12 months should receive a single dose of Tdap.
- For pregnant women: The Tdap vaccine is now recommended for all women in the third trimester (ideally 27th through 36th week of their pregnancy), even if they have previously received Tdap vaccine.

Side Effects

Pain at the injection site was the most frequently reported local adverse event from the primary adult safety trial conducted in adults who received either a single dose of ADACEL or Td. The most frequently reported systemic adverse events were headache, generalized body aches, and fatigue. Fever was reported with similar low frequency (approximately 1 percent) in both groups. Serious adverse events were reported in 1.9 percent of the vaccinated adults. There were no cases of whole-arm swelling.[45,46]

Strategies for Administration

The objectives of the most recent ACIP Tdap recommendations for adults, HCP, and pregnant or postpartum women are to protect the vaccinated adult against pertussis and reduce the reservoir of pertussis in the population. The strategy is to use Tdap as a one-time alternative to tetanus and diphtheria toxoids adsorbed for adult use (Td) in persons for whom the pertussis component is also indicated.[45,46]

Spacing with Other Immunobiologics

Tdap can be given simultaneously with any other vaccine, using different syringes and injected at different anatomical sites. Some experts recommend administering no more than two injections per muscle, separated by at least 1 inch.[46,47]

Use in Controlling Healthcare-Associated Transmission

There have been reports of using acellular pertussis vaccine during hospital outbreaks of pertussis.[31]

Currently, the vaccine is not licensed for use in adults during outbreaks of pertussis in hospitals.

Contraindications

- History of hypersensitivity to vaccine or any of its components
- History of encephalopathy (e.g., coma, prolonged seizures) not attributable to an identifiable cause within 7 days of administration of a pertussis vaccine

Precautions and Reasons to Defer Tdap

- GBS less than 6 weeks after a previous dose of a tetanus-containing toxoid

- Moderate to severe acute illness
- Unstable neurological condition in adult (e.g., cerebrovascular events and acute encephalopathic conditions) until resolved or stabilized
- History of Arthrous hypersensitivity reaction to a tetanus-containing vaccine administered less than 10 years previously
- Tdap is not licensed for adults aged >65 years[45,46]

Administration Schedule

- Tdap is licensed for one-dose administration, not for subsequent every 10-year boosters or wound prophylaxis.
- The one-time dose of Tdap is 0.5 mL administered IM (deltoid).
- Adults should receive a decennial booster (10 years later) after receipt of Tdap.
- Tdap is not licensed for multiple administrations.
- There are no data to support repeat administration of the vaccine.
- Short intervals between Td and Tdap: Tdap can be administered at an interval less than 10 years since receipt of last tetanus-containing toxoid vaccine to protect against pertussis. The dose of Tdap replaces the next scheduled Td booster.
- Special situations in adults:
  - Those with a history of pertussis should receive Tdap according to the routine recommendations.
  - Persons older than age 11 years who require a tetanus-toxoid containing vaccine as part of wound management should receive Tdap instead of Td if they have not previously received Tdap. If Tdap is not available or was administered previously, Td should be administered.
  - Those who have never received tetanus and diphtheria toxoid-containing vaccine should receive a series of three vaccines. The preferred schedule is a single dose of Tdap, a dose of Td 4 or more weeks later, and a second dose of Td 6 to 12 months later. Tdap can substitute for Td for any one of the three doses in the series.[29,45,46,47]

Post Vaccination Serological Testing

Not routinely done as, currently, no well-accepted serological correlates of protection for pertussis exist.

Effectiveness and Safety

According to ACIP, Tdap vaccines in the United States were licensed on the basis of clinical trials demonstrating immunogenicity not inferior to that of U.S.-licensed Td and the pertussis components of pediatric DTaP manufactured by Sanofi-Pasteur as well as an acceptable safety profile.[47]

Arthrous reaction can occur after a tetanus-toxoid-containing vaccine. ACIP lists Arthrous-like reaction from a previously administered tetanus-toxoid-containing vaccine within the previous 10 years as a precaution for Tdap.

Tdap prelicensure studies in adults support the safety of ADACEL. (However, ACIP points out that the sample sizes were insufficient to detect rare adverse events.) Close monitoring of vaccine safety from the Vaccine Adverse Events Reporting System (VAERS) and post licensure studies of Tdap have been

and will continue to be conducted. Such monitoring will enable detection of potential adverse reactions after widespread use of Tdap in adults.[46,47]

Unresolved Issues

As this is a recently licensed vaccine, there are areas of further information needed to assess long-term follow-up issues.

- Need for data on the burden of pertussis among adults and the impact of the Tdap vaccination policy
- Post licensure studies and surveillance to evaluate changes in the incidence of pertussis, the uptake of Tdap, and the duration of effectiveness of Tdap vaccine
- Safety and immunogenicity of Tdap in adults >65 years of age, pregnant women, and their children
- Effectiveness of deferring pertussis prophylaxis among recently vaccinated HCP exposed to pertussis
- Safety, effectiveness, and duration of protection of repeated Tdap doses
- Improved pertussis diagnostic tests
- Determination and evaluation of immunological correlates of protection for pertussis[31]

Commonly Asked Questions

- If HCP receive Tdap and then are exposed to someone with pertussis, is it appropriate to treat the HCP prophylactically or consider the HCP immune? Follow the PEP protocol for pertussis. There have been no new changes in pertussis PEP with the licensure of Tdap.
- Will Tdap replace the Td booster that is routinely recommended every 10 years? At this time Tdap is only approved for one dose except for those during pregnancy.
- If HCP have a history of pertussis infection as a child, is Tdap vaccine recommended for this HCP? HCP with a previous history of pertussis, who have not received Tdap, should receive Tdap according to routine recommendations.
- Should adult HCP get a pertussis booster if their institution is experiencing an outbreak of pertussis? Until studies specify the optimal management of exposed vaccinated HCP or a consensus of experts is reached, healthcare facilities should continue use of PEP for vaccinated HCP with unprotected pertussis exposures.

VACCINIA

Vaccinia vaccine has been included in this chapter for several reasons. First, there are routine, nonemergency indications for use of this vaccine against smallpox and other viruses in the *Orthopoxvirus* genus.[33] Second, smallpox has been designated by the CDC as a Category A agent, and therefore it has a higher potential for use as an agent of bioterrorism, against which the United States needs to protect its citizens.[48] After the anthrax bioterrorism attacks in 2001, a volunteer U.S. Civilian Smallpox Preparedness and Response Program (USCSPRP) resulted in approximately 40,000 civilian personnel from all 50 states (including 17,000 hospital healthcare staff and 13,000 public health response team members) receiving the vaccine. Selected military personnel are administered the smallpox vaccine. Finally, in an emergency smallpox situation, public health officials will likely issue additional recommendations regarding use of smallpox vaccine.

Vaccine

Routine smallpox vaccination among the American public stopped in 1972 after the disease was eradicated in the United States. Until recently, the U.S. government provided the vaccine only to a few hundred scientists and medical professionals working with smallpox and similar viruses in a research setting.

After the events of September and October 2001, however, the U.S. government took further actions to improve its level of preparedness against terrorism. One of many such measures—designed specifically to prepare for an intentional release of the smallpox virus—included updating and releasing a smallpox response plan. In addition, the U.S. government has enough vaccine to vaccinate every person in the United States in the event of a smallpox emergency.[49]

Indications

The categories of indications for use of vaccinia vaccine are divided into routine nonemergency; USCSPRP; and emergency recommendations.

- Routine nonemergency: Vaccinia vaccine is recommended for laboratory workers who directly handle cultures or animals contaminated or infected with non-highly attenuated vaccinia virus, recombinant vaccinia viruses derived from non-highly attenuated vaccine strains, or other orthopoxviruses that infect humans. The vaccine should be considered for HCP who have contact with patients with smallpox or who have received the smallpox vaccine and in situations in which adherence to infection prevention procedures may be compromised.[33]
- USCSPRP: In February 2003, the CDC initiated a call for volunteers to form healthcare response teams to care for the nation's citizens in the event of a smallpox event. Subsequent to 2003, vaccination of response team members has continued, although in much lower numbers. In this program, volunteers need to be carefully screened prior to vaccination and should discuss this decision with their healthcare providers. Extensive guidelines for persons considering vaccination in this program are available.[48]ACIP issued a statement in support of the pre-event program as long as it is carried out within the currently recommended response teams and state and local response plans, as well as according to current vaccination recommendations and protocols. ACIP stated, "At this time, it is unwise to expand beyond its current pre-event smallpox vaccination recommendations because of the new and unanticipated safety concerns, i.e., myo/pericarditis, whose extent and severity, particularly of long-term sequelae, are not yet known."[49]
- In an emergency situation, in which a smallpox agent has been intentionally released or if a susceptible individual has been exposed to a smallpox case, no absolute contraindications regarding vaccination exist. In such cases, any contraindications must be weighed against a potentially fatal smallpox infection[33]and public health officials will likely release additional guidelines for vaccination.

Side Effects

The following are listed as common adverse reactions from the smallpox vaccine:

- Inoculation site signs and symptoms, such as pain, redness, pruritus, or pyogenic infection at vaccination site
- Swelling and tenderness of regional lymph nodes
- Malaise
- Fatigue

- Fever
- Myalgias
- Headache

The preceding adverse events are less frequent in revaccinated persons than first-time vaccine recipients.

More Severe Adverse Events

- Inadvertent inoculation at other sites (most common are face, nose, mouth, lips, genitalia, and rectum)
- Self-limited skin rashes not associated with vaccinia replication in skin, including urticaria and folliculitis
- Encephalitis, encephalomyelitis, and encephalopathy
- Severe disability, permanent neurological sequelae
- Progressive vaccinia (vaccinia necrosum), generalized vaccinia, severe vaccinial skin infections, erythema multiforme major (including Stevens-Johnson syndrome), and eczema vaccinatum
- Myocarditis and/or pericarditis, ischemic heart disease, and nonischemic, dilated cardiomyopathy
- Ocular complications (including but not limited to keratitis and corneal scarring) and blindness
- Transmission of vaccinia virus to contacts[33]
- Death (including death of unvaccinated persons who have contact with vaccinated individuals)

Precise breakdowns of the frequency of serious adverse events by vaccine, and whether first-time or re-vaccinees are available for review.[50,51]

Precautions

ACIP recommends that persons be excluded from receiving smallpox vaccine for either nonemergency indications or to participate in the Smallpox Preparedness and Response Program who have known underlying heart disease, with or without symptoms; or have three or more of the following risk factors for ischemic heart disease: hypertension, high cholesterol, diabetes, heart disease in a first-degree relative (e.g., mother, father, brother, or sister), or smoke cigarettes.[50]

Strategies for Administration

The preferred sites of vaccine administration are into the skin over the insertion of the deltoid muscle in the upper arm. The skin should not be cleaned with alcohol or any other chemical agents prior to vaccination unless grossly contaminated. In such cases, the alcohol must be allowed to dry completely or it may inactivate the vaccine.

Persons who administer the vaccine should receive education on the proper technique. The CDC maintains an extensive and updated website with guidelines, recommendations, training videos, and instructions for HCP. The vaccine is administered via a multipuncture technique with a sterile bifurcated needle (licensed by the FDA for use with and supplied in the vaccine package). The bifurcated needle is dipped into the vaccine vial once and, when removed, contains a droplet with the recommended dosage of the vaccine. Holding the bifurcated needle perpendicular to the skin, 15 punctures are made into the

insertion site with strokes vigorous enough to allow a trace of blood to appear within a diameter of approximately 5 mm.

The vaccine site should be kept clean and dry. The CDC website contains detailed information for those who administer the vaccine, which include vaccine preparation, reconstitution, administration, storage, and instructions for interpreting the vaccination response.

Revaccination

ACIP recommends that persons at continued high risk of exposure to smallpox, such as research laboratory workers handling the virus, should receive repeat smallpox vaccination every 3 years.[48,50]

In October 2008, the CDC issued interim guidance for revaccination of persons vaccinated during the USCSPRP:

- Revaccination of persons who received vaccine during the UCSPRP is recommended on an as-needed, and what the CDC has termed, “out-the-door” basis (only after a determination of a credible smallpox threat to public health has been assessed and prior to the volunteers engaging in activities placing them at risk of smallpox virus exposure). This situation would only apply to those initially vaccinated during the implementation of this program and who had evidence of a documented vaccine “take” (successful vaccination).
- In addition, the CDC recommends revaccination of persons who administer smallpox vaccine to others, every 10 years.

Spacing with Other Immunobiologics

If possible, HCP scheduled to receive an annual purified protein derivative TST for tuberculosis screening should not receive the skin test until more than 1 month after smallpox vaccination.[48]There is a possibility that the vaccine may interfere with the tuberculin blood test as well.

Use in Controlling Healthcare-Associated Transmission

In 2003, an outbreak of monkeypox occurred in the United States after importation of exotic rodents, subsequently infected prairie dogs, were sold as pets. As a result of secondary cases of monkeypox in humans, at least 23 persons were vaccinated post exposure with smallpox vaccine, and the CDC issued interim recommendations regarding the use of smallpox vaccine.[51]However, at this time there are no recommendations for use of the vaccine post exposure. For emergency situations, it is likely that the vaccine will be used for those at high risk (see Emergency Indications).

Categories of Contraindications[33,48,52,53]

Emergency indications: There are very few absolute contraindications in the event of an emergency situation, resulting in persons with high risk for smallpox. In addition, it is important to note that those who are at greatest risk of experiencing serious complications after vaccination might also be those at greatest risk for smallpox death. Thus, the risk of serious complications must be weighed against that of experiencing a potentially fatal smallpox infection.[33]

Routine, nonemergency, and/or USCSPRP: Because the vaccinia virus can be spread to others from the site of a recently vaccinated individual, some contraindications apply to both potential vaccinees and their household contacts (including persons with prolonged intimate contact with the potential vaccines).

This also includes persons who may have direct contact with the vaccination site, such as sexual contacts. Other contraindications apply only to potential vaccinees.[33,50,51]

Contraindications

Live vaccinia virus can be transmitted to persons in close contact with vaccines; thus, the risks for experiencing the following severe adverse events apply to vaccinees and their close/household contacts.

Risks of severe adverse events are increased in vaccinees with the following conditions:

- Cardiac disease (current or past history).
- Eye disease treated with topical steroids.
- Congenital or acquired immune deficiency disorders, including taking immunosuppressive medications.
- Eczema (or history of eczema), or other acute or chronic exfoliative skin conditions.
- Pregnancy: The vaccine virus caused severe fetal vaccinia and death. If a woman is vaccinated during pregnancy, becomes pregnant within 28 days of vaccination, or if a vaccinee lives in the same household or is a close contact of a pregnant woman, the vaccinee should be counseled regarding the potential harm to the fetus.
- Breastfeeding mothers. It is not known whether the vaccinia virus or its antibodies are excreted in human milk. However, the risk of inadvertent inoculation is increased with the close physical contact involved with breastfeeding.
- Infants <12 months of age (the risk of serious adverse events following vaccination is higher in infants) and live virus can be inadvertently transmitted to an infant from a lactating mother.
- Previous severe reaction to smallpox vaccine or any of its components.
- ACIP advises against nonemergency use of the vaccine in persons <18 years of age.
- ACIP recommends that persons be excluded from the pre-event smallpox vaccination program who have known underlying heart disease, with or without symptoms, or if they have three or more known major cardiac risk factors—hypertension, diabetes, hypercholesterolemia (high cholesterol), heart disease at age 50 in a first-degree relative, and smoking.[50]
- Persons with known or possible latex sensitivity, as the vaccine vial stopper is made of dry natural rubber.

Emergency Indications (Post-release Vaccination)

According to the CDC and ACIP, all contraindications to vaccinia vaccination would be reconsidered during a smallpox emergency, and persons would be advised by public health authorities in such an event. Groups for which such vaccination would be indicated include:

- Persons exposed to the initial release of the virus
- Persons who had face-to-face, household, or close-proximity contact (<6.5 feet or 2 meters) with a confirmed or suspected smallpox case at any time from onset of the case's fever until all scabs have separated
- Personnel involved in the direct medical or public health evaluation, care, or transportation of suspected smallpox cases
- Laboratory personnel who collect or process clinical specimens from confirmed or suspected cases

- Other persons with increased likelihood of contact with infectious materials from a smallpox patient (e.g., personnel responsible for medical waste and/or linen disposal or disinfecting a room that houses smallpox cases)[33]

It is imperative that individuals refer to guidelines from public health officials that would be provided in an emergency smallpox situation.

Post Vaccination Serological Testing

The level of antibody that protects against smallpox is unknown. In addition, the level of antibody required for protection against vaccine virus infection is also unknown. No current recommendations regarding use of serological testing are available.

Effectiveness and Safety

Smallpox vaccine is indicated for active immunization against smallpox disease in persons determined to be at high risk for infection. In an emergency situation, for a person exposed to smallpox, the risk of death from smallpox versus the risk of severe complication from the vaccine must be weighed.

- Generalized rashes are not uncommon following vaccination and are usually self-limiting.
- Ocular and nonocular inadvertent inoculation is the most common side effect, resulting when the virus is transferred from the vaccine site to another site on the vaccinee. This can be prevented by careful hand hygiene and care of the vaccination site.
- Myocarditis/pericarditis occurs at a rate of 5.7 cases/million primary vaccinations.
- The majority of vaccinees have experienced at least one or more adverse event, with 10 percent of primary and 3 percent of re-vaccinees experiencing at least one severe adverse event.
- Vaccinia immunoglobulin (VIG) is available from the CDC for specific severe adverse reactions to the smallpox vaccine.[51]The data from the CDC smallpox website indicates that VIG was only released once between January 24, 2003, and April 30, 2005, during the USCSPRP.

A recent study conducted among adults vaccinated after 2001 indicated overall and serious adverse event rates of 217 and 26 per 100,000 vaccinees, respectively.[54]Epidemiological studies have supported a causal relationship between myo/pericarditis and smallpox vaccination. No new smallpox vaccine-associated clinical syndromes have been identified.[55]

VARICELLA

Vaccine Type

Currently one preparation of a live attenuated varicella vaccine, Varivax (Merck) is licensed for use in adults in the United States. Varivax is a lyophilized preparation.

Indications

Varivax vaccine is indicated for protection against varicella and its complications. The most recent ACIP guidelines have expanded the list of indications to all healthy persons >13 years, HIV-infected adolescents, and adults with specific CD4 T-lymphocyte counts, postpartum assessment and vaccination, and approved criteria for evidence of immunity.[56,57]Healthcare institutions should ensure that all HCP

have evidence of immunity to varicella.[5]Adults who may be at increased risk of either acquiring or transmitting varicella who do not have evidence of immunity, should receive special consideration for vaccination. This includes susceptible persons older than 13 years in the following high-risk groups.[56,57]

- HCP
- Household contacts of immunocompromised individuals
- Persons who live or work where transmission of varicella zoster virus (VZV) is likely (e.g., teachers of young children, day care employees, and residents and staff members in institutional settings)
- Persons who live or work in environments where transmission can occur (e.g., college students, inmates and staff members of correctional institutions, and military personnel)
- Nonpregnant women of childbearing age (women should be advised to avoid pregnancy for 1 month after each dose of the vaccine)
- Adolescents and adults living in households with children
- International travelers
- Recommended for use in susceptible persons following exposure to varicella, within 3 days and possibly up to 5 days after exposure
- ACIP recommends the use of varicella vaccine for outbreak control for exposed susceptible persons[56]
- Most recently, ACIP has described several special considerations for vaccination, including HIV-infected adults with CD4T-lymphocyte counts of ≥200 cells/μL (two doses 3 months apart); some situations where mild degrees of immune suppression are present (e.g., those with impaired humoral immunity); and susceptible postpartum nursing mothers.[56]

Evidence of Immunity for HCP

- Written documentation of vaccination with two doses of varicella vaccine.
- Laboratory evidence of immunity or laboratory confirmation of disease.
- Diagnosis or verification of a history of varicella disease by a healthcare provider.
- Diagnosis or verification of a history of herpes zoster by a healthcare provider.

Side Effects

Rash, fever, and injection-site soreness have been the most frequently reported adverse events in the post-licensure period. See Table 103-8 for a summary of adverse events.[58]

Table 103-8.Post-varicella Immunization Side Effects in Adults[58]

Table 103-8 Post-varicella Immunization Side Effects in Adults

Reaction	Percent Post First Dose	Percent Post Second Dose
Fever ≥101°F	10.2 percent	9.5 percent

Injection-site complaints	24.4 percent	32.5 percent
Varicella-like rash (injection site)	3 percent	1 percent
Varicella-like rash (generalized)	5.5 percent	0.9 percent

*Evidence of immunity is defined as either diagnosis of varicella by a healthcare provider or a healthcare provider verification of a history of varicella disease (rather than parental or self-report). U.S. birth before 1980 is not considered evidence of immunity for HCP, pregnant women, and immunocompromised persons.**56**

Strategies for Administration

Serological screening of personnel with negative or uncertain history of varicella is likely to be cost effective prior to vaccination.[46]Healthcare facilities might consider serological testing of all personnel regardless of history, as a small portion of those with positive disease history might be susceptible.[56]

Vaccine can be offered to susceptible HCP on initial employment or at annual intervals concurrent with other employment-related healthcare activities (i.e., annual TST or annual symptom review for tuberculosis).

Policies for management of vaccinated HCP should be developed for each institution. These policies should be added to those already in place for handling varicella exposures. There are numerous issues to be included in such policies, such as definitions of exposure to varicella; serological testing for immunity to varicella; whether to require or recommend vaccination to nonimmune employees; how to manage vaccinated HCP in the immediate post vaccination period and in future exposures to wild-type varicella; and how to handle patients and HCP who develop vaccine rash. There are many questions to be considered in formulating these policies (see “Further Issues for Consideration”).

Spacing with Other Immunobiologics

Varivax can be given at the same time (using separate anatomical sites and syringes) or within 30 days of MMR without increasing adverse reactions. ACIP guidelines state that the simultaneous administration of most widely used live attenuated and inactivated vaccines has not resulted in impaired antibody responses or increased adverse effects with this vaccine.[18,56]

Immunoglobulin, including varicella zoster immunoglobulin (VZIG), should not be given for at least 2 months after vaccination with varicella vaccine. Vaccination with varicella vaccine should be deferred for at least 5 months after administration of blood or plasma infusions, or administration of any immunoglobulin, including VZIG.[56]

Use in Controlling Healthcare-Associated Transmission

To prevent healthcare-associated transmission, healthcare facilities should ensure that all susceptible HCP have been vaccinated with varicella vaccine. Policies must be developed to manage employees who may develop vaccine rash because of the very small risk of vaccine virus transmission.[5,56]

ACIP recommends use of varicella vaccination within 3 to 5 days after exposure for unvaccinated HCP without evidence of immunity to modify the disease. Vaccination more than 5 days after exposure is also

indicated, as it protects against subsequent exposures if the current exposure did not result in infection. Persons at increased risk for severe varicella who have contraindications to varicella vaccine should receive VZIG within 96 hours of exposure.

Policies must be developed to manage employees who may develop vaccine rash because of the very small risk of vaccine virus transmission.[5,56] ACIP recommends that if a vaccine-related rash occurs in HCP, the HCP should avoid contact with susceptible persons who are at risk for severe disease/complications. This work restriction should continue until all lesions have crusted or disappeared or no new lesions have occurred within a 24-hour period.[56]

Contraindications (to Single-antigen Vaccine in Adults)[18,56,58]

- Persons with a history of hypersensitivity (e.g., anaphylaxis) after a previous vaccine dose or to any component of the vaccine, including gelatin and neomycin.
- Persons with any malignant condition, including blood dyscrasias, leukemia, lymphomas of any type, or other malignant neoplasms affecting bone marrow or lymphatic systems.
- Pregnant women (and vaccinated women should be counseled to avoid pregnancy for one month after each dose of the vaccine). Women who become pregnant within 1 month of vaccination should be counseled about potential effects to the fetus.
- Persons with substantial suppression of cellular immunity.
- Anyone with a family history of congenital or hereditary immunodeficiency in first-degree relatives unless the immune competence of the potential vaccine has been verified clinically or by a laboratory.
- Persons receiving high-dose systemic immunosuppressive therapy, including those on oral steroids ≥2 mg/kg of body weight or a total of 20 or more mg/day of prednisone or equivalent for persons who weigh >10 kg, when administered for 2 or more weeks. Vaccination can result in a more extensive vaccine-associated rash or disseminated disease in these individuals.[58]

Precautions

- Vaccination of persons who have acute severe illness, including febrile respiratory illness or other infection, including untreated active tuberculosis, should be postponed until the person has recovered. However, TST is not a prerequisite for varicella vaccination. The decision to delay vaccination depends largely on the severity of symptoms and etiology of the disease.
- Varicella vaccines should not be administered for 3 to 11 months after administration of blood, plasma, or immunoglobulin (but not washed red blood cells) because of potential inhibition of immune response by passively transferred antibodies. (The time interval depends on the product.)[18]
- As a precautionary measure, epinephrine injection (1:1,000) should be available for immediate use should an anaphylactic reaction occur.
- The manufacturer recommends vaccine recipients avoid the use of salicylates for 6 weeks after vaccination, as Reye's syndrome has been reported after the use of salicylates during natural varicella infection.[58]

Administration Schedule

All healthy adult HCP without evidence of immunity to varicella should receive two 0.5-mL doses of single-antigen vaccine by subcutaneous administration, 4 to 8 weeks apart. The preferred site of

administration is the deltoid muscle.

Additional administration and handling information:[58]

- Not for intravenous injection
- Diluent should be stored separately at room temperature or in a refrigerator
- Vaccine must be stored frozen before reconstitution at an average temperature of about 5°F (–15°C) or colder.
- Once reconstituted, the vaccine should be administered immediately. Discard if reconstituted vaccine is not used within 30 minutes.
- Do not freeze the reconstituted vaccine.
- Duration of protection is unknown at present, and the need for booster doses is not defined; additional studies are needed in this area.

Post Vaccination Serologic Testing

Routine testing for varicella immunity following two doses of vaccine is not recommended for the management of vaccinated HCP. Approximately 99 percent of adults are seropositive after the second dose. However, seroconversion does not always result in full protection against disease.[56]Currently, there are no data available for adults regarding correlates of protection.

Effectiveness and Safety

From prelicensure studies, efficacy of the vaccine in protecting adults from varicella after household exposure was estimated to be 80 percent.[58]Postlicensure studies assessing the effectiveness of the vaccine in preventing moderate to severe varicella have consistently demonstrated high effectiveness.[58]

Pre- and postlicensure studies have demonstrated that one dose of the single-antigen vaccine is approximately 85 percent effective in preventing varicella, and 95 percent effective in preventing severe varicella disease. Breakthrough varicella disease that occurs after vaccination is mild.[56]

ACIP defines breakthrough disease as “a case of infection with wild-type VZV occurring > 42 days after vaccination.”[56]Breakthrough infection was reported in several postlicensure studies of adolescent and adult vaccine recipients, to occur between 8 and 10 percent, although breakthrough disease was substantially less severe among vaccinated than unvaccinated persons.[59,60]

For the almost 50 million doses distributed in the United States between 1995 and 2005, the overall adverse reporting rate was 52.7 cases/100,000 doses and the serious adverse event reporting rate was 2.6/100,000 doses. Although rare, serious adverse events included pneumonia, hepatitis, severe disseminated varicella infection, and secondary vaccine-virus transmission. It is noteworthy that except for vaccine virus transmission, the other severe events occurred in immunocompromised persons or those with serious medical conditions not known at the time of vaccination. Rash, fever, and injection-site reactions were the most commonly reported adverse events detected during postlicensure safety surveillance.[56]

Vaccinees may potentially be capable of transmitting vaccine virus to close contacts. This has occurred in vaccinees that developed a rash after vaccination. Vaccinated HCP with a vaccine-related rash should

therefore avoid close contact with susceptible high-risk individuals, such as newborns, pregnant women, and immunocompromised persons.[56](See also Strategies for Administration.)

Should inadvertent vaccination to a varicella-immune individual occur, the vaccine has been well tolerated in seropositive individuals, with no serious adverse effects.

Unresolved Issues

- The length of protection from varicella-containing vaccines remains unknown.
- Ongoing surveillance and studies are needed to determine the need for and timing of additional doses in the future.
- The effect of the use of varicella vaccine on the epidemiology of the disease, and the ability of clinicians to recognize breakthrough illness needs to be monitored in the future.
- The long-term effect of varicella vaccine on the incidence of herpes zoster, including those vaccinees exposed to varicella, is not presently known.[58]

Additional Issues

ACIP recommends that healthcare institutions should establish protocols and recommendations for screening and vaccinating HCP and for management of HCP after exposures in the workplace.

Questions that should be addressed and/or considered in formulating healthcare policies for vaccinating HCP and patients include:

- What is the definition of a varicella exposure? Does the definition differ between household versus hospital? Is there a minimal time limit for an exposure (i.e., 2 minutes is not considered an exposure but 10 minutes is)? Is exposure to a person with vaccine rash treated differently from an exposure to wild varicella virus?
- What is accepted as a positive history of varicella? ACIP has recently added criteria for evidence of immunity. For HCP, pregnant women, and immunocompromised persons, there are stricter criteria.[56]
- How many nonimmune employees are employed at the institution? How many varicella exposure incidents occur on average every year? Does the patient population consist of a significant number of high-risk susceptible persons? Do the answers to these questions warrant alternative approaches to managing varicella-exposed nonimmune employees rather than automatic work furloughs?
- What serological test is utilized for determining varicella susceptibility? How are borderline, equivocal, or questionable results handled?
- How will employees be screened for varicella? Will vaccinated employees be considered immune to varicella? Will any serological testing be done in such employees (i.e., after two doses of vaccine, after exposure to wild virus, or not at all)?
- Will vaccinated employees be allowed to work without restrictions in the immediate postvaccination period? If not, what will the restrictions include?
- Will vaccinated employees be considered immune after the first dose, the second dose, or not at all? Will restrictions to HCP only apply if vaccine rash develops? Will restrictions differ if the rash is localized at the injection site or generalized?
- What are the facility's policies regarding precautions for persons in whom a rash develops after vaccination?

Sample strategies for management of vaccinated HCP and patients need to include possibilities of vaccine rash development in the vaccinee, exposure to wild virus, breakthrough disease, and transmission of vaccine virus to unvaccinated persons.

The following strategies may be considered separately or in combination; other strategies may be devised by individual institutions.

- Consider all vaccinees to be immune to varicella—no restrictions regardless of whether vaccine rash develops or if vaccinee is exposed to wild VZV.
- Restrict vaccinated HCP from caring for high-risk susceptible individuals between times of first dose until 1 month after second dose.
- Restrict vaccinated HCP from caring for high-risk susceptible individuals only if vaccine rash develops, whether rash is generalized or localized to the injection site.
- Treat vaccinated HCP as if they are susceptible to varicella. In the immediate postvaccination period, should vaccine rash develop, options to consider for the employee include:
- Restrict from work until lesions from the rash have completely dried and crusted.
- Allow employee to work in areas without high-risk susceptible persons until the lesions have completely dried and crusted.
- Allow employee to work in nonclinical area until all lesions have dried and crusted.
- Do not restrict the employee in any way.
- Options for treating vaccinated HCP exposed to wild VZV:
  - No restrictions—consider employee immune.
  - Send employee home from day 8 to 21 post exposure for after each exposure to wild VZV.
  - Allow employee to work while face-masked from day 8 to 21 post exposure and to self-screen daily for symptoms; send employee home if disease develops. If disease develops, it would not be considered an exposure if employee complied with masking. This option has been utilized with success for managing hospital employees and patients nonimmune to varicella for numerous years. Algorithm-based policies have been developed for using this same premise for vaccinated employees and patients exposed to varicella.[61]
  - Allow employee to work without restrictions; allow self-screening for symptoms with work furlough if symptoms develop. However, should disease develop in this case, an exposure may occur because persons who develop varicella can be contagious several days before rash develops.
- Allow employee to work in an area without high-risk susceptible persons; send home if rash develops.

Note: For any of the preceding options, careful consideration should be given to making such options consistent with current available information on the vaccine as well as existing hospital policies, patient and employee susceptibility in individual institutions, and the incidence of varicella in the institution.

Caution: In this current age of concern regarding biological terrorism, it is imperative that HCP are well informed about the differences between varicella and smallpox rashes. This concern underscores the importance of improving varicella vaccination efforts in both HCP and patients to avoid confusion.

Commonly Asked Questions

- If I am a healthcare provider who is nonimmune to varicella, but I have an immunocompromised child at home, is it safe for me to get the varicella vaccine? This is an important question. The vaccine is particularly indicated for susceptible family members of immunocompromised individuals. Data to date

show that there is very limited potential for vaccinees to spread virus to susceptible contacts. The risk of transmission from immunocompromised vaccinees with rash may be higher. In one study of children with leukemia who were vaccinated and developed rash, 15 (17 percent) of their healthy siblings developed varicella vaccine infection, although only 11 developed even a mild rash. The data to date suggest that healthy vaccinated adults have very limited potential to transmit vaccine virus to susceptible contacts. Where this has happened, seroconversion has either been asymptomatic or accompanied by very mild rash.

- Can the vaccine cause herpes zoster? The manufacturer calculated an incidence of 18.5 cases of herpes zoster/100,000 person years, based on follow-up clinical trials in adolescents and adults.[58]

  Multiple studies and surveillance data have not demonstrated any consistent trends in the incidence of herpes zoster since the vaccine program was initiated in 1995.[56]

- Can the vaccine be used for postexposure prophylaxis? ACIP recommends the vaccine for use in susceptible persons following exposure to varicella.[56]In exposed susceptible persons with contraindications to the vaccine, VZIG can be administered up to 96 hours post exposure.

- What should we do if HCP develop a vaccine-related rash? ACIP advises that HCP who develop a rash after immunization should avoid contact with immunocompromised individuals with a high risk of disease and complications, until all lesions resolve or until no new lesions have appeared within a 24-hour period.[56]

- Where can I get more information on varicella vaccine? ACIP published a revised statement on the use of varicella vaccine.[56]

GENERAL RECOMMENDATIONS FOR UNIMMUNIZED ADULT HEALTHCARE PERSONNEL

HCP should be immunized against Hepatitis B, influenza, measles, mumps, rubella, tetanus-diphtheria-pertussis, and varicella. HCP are not at increased risk of acquiring tetanus in comparison with the general population but should nonetheless follow ACIP guidelines (see Table 103-9). Guidelines for primary vaccination of adults not immunized at the recommended time in early infancy are shown in Table 103-10. The guidelines for adults differ from those of children because of age-specific risks of disease and complications.

Table 103-9.Immunization Schedule for HCP[5]

Table 103-9 Immunization Schedule for HCP

Vaccine	Indication	Schedule
Hepatitis A	Laboratory/primate workers	1 mL IM at 0, 6 months
Hepatitis B	Occupational exposure to blood, blood products, or bodily secretions	Three doses of 1 mL IM at 0, 1, and 6 to 12 months
Hepatitis A & B	As for Hepatitis A and Hepatitis B	1 mL IM at 0, 1, and 6 months

Influenza	Persons attending high-risk patients (e.g., elderly) Inactivated vaccine LAIV	1 dose of 0.5 mL IM annually Intranasal dose of 0.5 mL annually (split between both nostrils)
MMR Measles Mumps Rubella	Adults born after 1957 without a history of physician-diagnosed measles, serologic immunity, or documentation of having received two doses of vaccine Adults born after 1957 without a history of mumps, serologic immunity, or documentation of having received vaccine Unimmunized women of childbearing age and healthcare personnel	0.5 mL SQ at 0, and at least 1 month later 0.5 mL SQ once 0.5 mL SQ once
Td	Persons without a history, or an unknown history of Td immunization or >10 years since last dose	Unimmunized: three doses of 0.5 mL IM at 0, 1 to 2, 6 months Booster: one dose every 10 years
Tdap	HCP with direct patient contact, healthy adults 19 to 64; close contacts of those <1 year	0.5 mL IM one-time dose (can be substituted for any Td dose)
Varicella	Adults nonimmune to varicella	0.5 mL SQ at time 0 and 4 to 8 weeks later

IM, intramuscular; SQ, subcutaneous.

Some products require more than one dose to ensure a protective adequate antibody response. In addition, some products, such as tetanus toxoid, require periodic booster doses throughout life to maintain satisfactory protection.

The intervals between doses shown in Table 103-10 are considered optimal and are intended to induce immunity as rapidly as possible. Longer intervals do not diminish the antibody response.

Adults who have received some, but not all, of the recommended doses should simply complete the interrupted series without starting over or receiving extra doses. Conversely, shorter intervals may lessen the antibody response and increase the risk of local or systemic reactions (e.g., tetanus and diphtheria toxoids, Hepatitis B).

Table 103-10 Immunization Schedule for Adults Not Immunized at the Recommended Time in Early Infancy[18]

Vaccine				Td*
	MMR#1	MMR#2	IPV #3	
	IPV #1	IPV #2	Td #3	
	Td #1	Td #2		

Time of administration	First visit	1 to 2 months later	6 to 12 months later	10 years later and every 10 years thereafter

IPV, inactivated polio vaccine; MMR, measles, mumps, and rubella; Td, tetanus and diphtheria toxoids for adults; Tdap, tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine.

*Tdap should be received once and can be substituted for any Td dose.

Dosing Recommendations

Immunobiologics should be stored, dosed, and administered properly to ensure maximum safety and efficacy (Table 103-11). Additional details are available in the respective manufacturers' prescribing information.

- Storage conditions are important determinants of potency.
- Most immunobiologics should be refrigerated (i.e., 2° to 8°C or 36° to 46°F). Freezing may destroy potency of some vaccines. Exception is varicella vaccine, which is stored frozen.
- MMR should be protected from light and used within 8 hours of reconstitution.
- Varicella vaccine must be used within 30 minutes of reconstitution. Must be kept frozen until ready to use.
- Route of administration impacts on both efficacy and safety:
- Most vaccines are inactive if administered by mouth.
- Vaccines containing adjuvants should be administered deep into the muscle mass to avoid local irritation and maximize immunogenicity. Therefore, an adequate needle length should be used to ensure deep intramuscular injection.[7]
- The site of injection should be chosen carefully to avoid local, neural, vascular, or tissue injury.
- In adults, the deltoid area is the preferred site of administration for both subcutaneous and intramuscular injections.
- The buttock should be avoided because of the risk of injury to the sciatic nerve. Furthermore, administration of Hepatitis B vaccine in the buttocks has been associated with decreased immunogenicity, presumably because of inadvertent injection into the subcutaneous or deep fat tissue.
- Most commercially available vaccines may be given simultaneously on the same day, but not at the same site.
- Simultaneous administration of MMR, poliovirus vaccine, and tetanus and diphtheria toxoids does not diminish efficacy or safety of the individual vaccines in comparison with separate administration.
- Candidates for influenza virus and pneumococcal vaccines often overlap; these two vaccines may be given simultaneously, at separate sites, without increasing the risk of adverse effects. However, it should be noted that influenza virus vaccine is intended for annual use, whereas pneumococcal vaccine is usually given only once.

Table 103-11.Storage Conditions and Route of Administration for Adult Vaccines[18]

||table:11||

Doses of immunobiologics have been carefully selected based on theoretical considerations, controlled trials, and clinical experience. Some practitioners use smaller, divided doses in an effort to minimize the

risk of adverse reactions, but such practices may result in inadequate protection and increased local reactions. Conversely, higher doses may increase the risk of local or systemic reactions. ACIP strongly discourages any variation from the recommended volume or number of doses of any vaccine.

MENINGOCOCCAL DISEASE

Healthcare facilities should consider including vaccines to prevent meningococcal disease, typhoid, and polio for HCP who have certain conditions or who work in laboratories or regions outside the United States where the risk for work-related exposures exist. Healthcare-associated transmission of *Neisseria meningitis*is rare, but HCP have become infected after direct contact with respiratory secretions of infected persons and in a laboratory setting. HCP can decrease the risk for infection by adhering to precautions to prevent exposure to respiratory droplets and by taking antimicrobial chemoprophylaxis if exposed directly to respiratory secretions.

Vaccine Types

Two quadrivalent conjugate meningococcal vaccines (MCV4 and MPSV4) are licensed for persons aged through 55 years. Both protect against two of the three serogroups that cause the majority of meningococcal disease in the United States and against 75 percent of disease among adults. Both vaccines have similar safety profiles in clinical trials. However, MCV4 is not recommended routinely for all HCP.

Indications

A two-dose vaccine series is recommended for HCP with known asplenia or persistent complement component deficiencies, because these conditions increase the risk for meningococcal disease. HCP traveling to countries in which meningococcal disease is hyperendemic or epidemic also are at risk for infection and should receive vaccine. All other HCP who are at high risk due to their work conditions should receive a single dose of MCV4. Clinical microbiologists and research microbiologists who might be exposed routinely to isolates of *N. meningitides*should receive a single dose of MCV4 and receive booster doses every 5 years if they remain at increased risk. HCP aged >55 years who have any of the above risk factors for meningococcal disease should be vaccinated with MPSV4. HCP with known HIV infection are likely to be at increased risk for meningococcal disease and may elect vaccination. If these HCP are vaccinated, they should receive a two-dose vaccine series.

Postexposure Management of Exposed HCP

PEP is advised for all persons who have had intensive, unprotected contact (i.e., without wearing a mask) with infected patients (e.g., via mouth-to-mouth resuscitation, endotracheal intubation, or endotracheal tube management), including HCP who have been vaccinated with either the conjugate or polysaccharide vaccine.

Antimicrobial prophylaxis can eradicate carriage of *N. meningitidis*and prevent infections in persons who have unprotected exposure to patients with meningococcal infections.[62]Rifampin, ciprofloxacin, and ceftriaxone are effective in eradicating nasopharyngeal carriage of *N. meningitidis*. In areas of the United States where ciprofloxacin-resistant strains of *N. meningitidis*have been detected (as of August 30, 2011, only parts of Minnesota and North Dakota), ciprofloxacin should not be used for chemoprophylaxis.[63]Azithromycin can be used as an alternative. Ceftriaxone can be used during pregnancy. PEP should be administered within 24 hours of exposure when feasible; PEP administered >14 days after exposure is of limited or no value.[62]HCP not otherwise indicated for vaccination may be

recommended to be vaccinated with meningococcal vaccine in the setting of a community or institutional outbreak of meningococcal disease caused by a serogroup contained in the vaccine.

ESTABLISHING A HEALTHCARE PERSONNEL IMMUNIZATION PROGRAM

Rationale for a Healthcare Personnel Immunization Program

It should be a priority for healthcare institutions to provide as safe an environment as possible for both employees and the patients they serve. This includes prevention of disease transmission between HCP and patients, particularly those diseases that are preventable by immunization. HCP are at risk of acquiring several vaccine-preventable diseases in this type of setting. This fact alone should provide motivation for establishment of an effective immunization program for HCP. The rationale for establishing an HCP immunization program has been previously discussed.[5]

The CDC has listed seven elements of a Personnel Health Service for Infection Prevention to assist in effectively attaining infection prevention goals.[5]

1. Coordination with other departments (especially Infection Prevention)
2. Medical evaluations before placement of personnel
3. Personnel health and safety education
4. Immunization programs
5. Protocols for surveillance and management of job-related illnesses and exposures to infectious diseases
6. Counseling services for personnel regarding infection risks related to employment or special conditions (including work restrictions)
7. Maintenance of health records (data management and protection of confidentiality)

It is important to note how the other six elements are related to that of the fourth element, immunization programs. An effective immunization program must be intertwined with these elements, as is illustrated in this section of the chapter.

Goals of a Healthcare Personnel Immunization Program

An effective program should have the following as its goals:

- Achieving high rates of immunization: For those HCP-mandatory vaccines, as chosen by the individual institution, the desirable goal is 100 percent immunization. The only exceptions should be those persons with physician/practitioner-documented medical contraindications or acceptable proof of immunity.
- Devising and implementing specific vaccine policies: The institution must determine which diseases to include and formulate specific policies for immunization of HCP in that institution.
- Providing education about vaccines: This begins with employee/occupational health policies regarding the vaccine-preventable diseases at the specific institution. HCP need to be fully informed regarding the benefits and risks of a vaccine before receiving it. In addition, there must be continuing educational updates as new information on old vaccines emerges or new vaccines become available. Institution-specific data on HCP immunization rates and disease outbreaks caused by vaccine-preventable diseases at periodic intervals should be communicated to all HCP.
- Justifying the cost: A successful immunization program can justify its cost by demonstrating the cost effectiveness of prevention versus the cost of controlling disease outbreaks among patients and HCP

at the institution. ACIP's *Guide for Adult Immunization*states, "The high cost of controlling outbreaks of measles and rubella have been documented repeatedly, suggesting that even in the absence of a formal cost-effectiveness analysis, the benefits of vaccinating adults against these diseases may be substantial."[5]

Current Laws and Medicolegal Issues

- The Occupational Safety and Health Administration (OSHA) regulations: OSHA's Bloodborne Pathogen Standard (a federal standard; state-specific standards also apply) was passed in 1991 and revised in 2001. It requires that employers provide Hepatitis B vaccinations at no charge to HCP designated by each institution to be at risk for exposure. The mandate is for the vaccine to be offered; there is no requirement that it must be accepted. However, HCP who decline the vaccine are required to sign an "informed declination" form.[64,65]In addition, OSHA requirements outline specific employee training programs regarding the frequency, transmission, and illness patterns associated with bloodborne pathogens. This is an ideal time to reinforce the need for coverage against all vaccine-preventable diseases.
- Right-to-know laws: Some states have specific regulations outlining in detail the requirement to inform employees who may be exposed to workplace hazards (e.g., vaccine-preventable diseases), what the risks are, and how to minimize these risks. Every state has laws that entitle persons receiving any kind of medical treatment or medication to be fully informed regarding all indications, possible adverse effects, options, and benefits.
- Codified standards of care: Although not having the specific force of law, agencies and expert groups concerned with the public health or with the health of HCP have published consensus statements regarding HCP immunization. These statements form the "standard of care" that physicians and other practitioners are expected to follow. These standards of care can, in fact, be used to establish fault in legal proceedings. The CDC has proposed specific standards regarding the immunization of HCP against vaccine-preventable diseases.[5]The evidence on which these recommendations are based is categorized as I to III (defined in Table 103-12):
  - Formulate a written comprehensive policy on immunizing HCP (category IB).
  - Administer Hepatitis B vaccine to personnel who perform tasks involving routine and inadvertent contact with blood, other body fluids (including blood-contaminated fluids), and sharps (category IA).
  - Offer influenza vaccine annually to all eligible HCP to protect staff, patients, and family members and to decrease HCP absenteeism. Use of either TIV or LAIV is recommended for eligible HCP. During periods when inactivated vaccine is in short supply, use of LAIV is encouraged for eligible HCP (category IA).[16]
  - Ensure that all personnel have documented immunity to measles and administer measles vaccine to those who do not (category IA [refer to most current ACIP adult immunization schedule to meet this requirement]).
  - Administer mumps vaccine to all personnel without documented evidence of mumps immunity, unless otherwise contraindicated (category IA).
  - Determine whether personnel who may have direct contact with patients who may be excreting polioviruses, or who work in the laboratory handling specimens/cultures that might contain wild poliovirus, have completed a primary vaccination series against polio (category IA).

- For such personnel listed in the preceding, complete the series with enhanced inactivated polio vaccine (category IB).
- Vaccinate all personnel without documented immunity to rubella, with an appropriate rubella-containing vaccine (category IA).
- Administer varicella vaccine to susceptible personnel, especially those that will have contact with patients at high-risk for serious complications (category IA).

- As a further example, some institutions or expert groups have formulated formal statements regarding specific vaccine-preventable diseases. For example, the Infectious Diseases Society of America has published a consensus statement regarding measles immunity in HCP and, more recently, mandatory vaccination against influenza, with a provision for declination of vaccination based on religious or medical reasons.[5]The Joint Commission has long recommended that HCP who have contact with pregnant women should be immune to rubella. In 2007, The Joint Commission approved an infection prevention standard that requires accredited organizations to offer influenza vaccinations to staff, including volunteers and independent contractors, with close patient contact.[17]In 2008, the Association for Professionals in Infection Control and Epidemiology released a position paper on influenza immunization of healthcare personnel in which they recommend “influenza vaccine be required annually for all healthcare personnel with direct patient care.”[16]
- Vaccine information statements (VIS): The National Childhood Vaccine Injury Act (NCVIA) of 1986 applies to diphtheria, tetanus, pertussis, measles, mumps, rubella, polio, Hepatitis A, Hepatitis B, *Haemophilusinfluenzae*type B (Hib), trivalent influenza (inactivated and live), pneumococcal conjugate, meningococcal, rotavirus, human papillomavirus, and varicella vaccines. The NCVIA requires the use of vaccine information statements for these vaccines, that information about the immunization administered is permanently recorded, and that adverse events associated with these vaccines are reported. There are 10 points that must be presented in easily understood terms before immunization with the vaccines can be given.[66]

Table 103-12.Categorization Scheme for Recommendations[5]

||table:12||

These include the following:

1. Frequency, severity, and potential long-term effects of the disease to be prevented by the vaccine.
2. Symptoms or reactions to the vaccine that should be brought to the immediate attention of the healthcare provider.
3. Precautionary measures to reduce the risk for any major adverse effects to the vaccine that may occur.
4. Early warning signs or symptoms that may be possible precursors to such major adverse reactions.
5. A description of the manner in which to monitor such major adverse reactions to the vaccine that may occur.
6. A specification of when, how, and to whom any major adverse reaction should be reported.
7. The contraindications to (and basis for delay of) the administration of the vaccine.
8. Identification of the groups, categories, or characteristics of potential recipients of the vaccine who may be at significantly high risk for major adverse reaction to the vaccine compared with the general population.

9. A summary of the relevant federal recommendations for a complete schedule of childhood immunizations and the availability of the National Vaccine Injury Compensation Program.
10. Such other relevant information as may be determined by the secretary of the Department of Health and Human Services.

Barriers to Successful Immunization Programs

In addition to misconceptions regarding immunization, the following can be barriers to successful immunization:

- Institutional and organizational issues: If the institution does not support an immunization program for its employees, the chance for its success is diminished. Institutional support must be in the form of specific immunization requirements for its employees, effective monitoring of compliance, and financial backing for the program.
- Medical issues: Concern over adverse effects of vaccines can serve as a strong deterrent to immunization. This concern may be based on misconceptions regarding vaccines in general. However, it can also be related to specific legitimate medical contraindications present in the recipients. Institutions that require mandatory immunizations for specific diseases as a condition of employment may be faced with physician-documented contraindications to vaccination in some employees. Those that do not get immunized are then at risk of transmitting or acquiring vaccine-preventable diseases in the future. It is important to counsel such employees about the risks they may face and to provide work restrictions according to the most current infection prevention/occupational health guidelines after exposures.
- HCP issues: In addition to the medical issues listed previously, issues for HCP as a recipient of a vaccine can serve as a barrier to immunization. The fact that this group works in a medical setting can exacerbate some misconceptions about specific vaccines. One example would be that before the recombinant form of Hepatitis B vaccine was developed, there was concern by many HCP of the possibility of acquiring HIV infection from this vaccine. Another example is the fear of getting the swine flu from the influenza vaccine. In both examples, the fears are unwarranted. Nevertheless, they have contributed to poor compliance rates with vaccinations against these two diseases in HCP.

Components of a Successful Healthcare Personnel Immunization Program: The Role of the Infection Preventionist

In today's era of rising costs and shrinking budgets, the infection preventionist (IP) may be asked to wear many hats. It is not unusual to find a practitioner who may be responsible for infection prevention and control, employee health, risk management, performance improvement activities, or some combinations of these roles. Therefore, in delineating the role of the IP in a successful HCP immunization program, it is important to keep in mind that the extent of involvement in the following activities is related to the practitioner's specific job responsibilities.

Administrative

- Defining and articulating an immunization policy; the IP's input into the institution's policies regarding immunization can take several forms, including:
- Formulating the policies from the infection prevention department
- Formulating the policies in conjunction with the employee health department
- Reviewing and giving feedback on policies written by others (e.g. administration, personnel)
- Incorporating the most recent legislative mandates, guidelines, or standards of practice into policies

Whatever the forum, the IP should have adequate input into these policies.

- Continuously updating specified objectives: The IP must possess current knowledge about immunization as well as institutional events that may be related to the immunization program. It may be necessary to review the objectives of the immunization program at regular intervals to ensure that the information is current.
- Assigning responsibility for the program; possible ways for the IP to be involved in the institution's immunization program include:
- Responsible for entire program (policy development, monitoring of compliance, administration of the program, record-keeping, education)
- Responsible to oversee the employee health department's administration of the program
- Responsible for parts of the program
- Responsible for the education of employees regarding the program

Implementation

Depending on the specific responsibilities of the IP, the role in implementation of an immunization program may vary. At the same time, it is important to recognize the importance of the IP in contributing to the implementation of such programs.

- Convenience of immunization: HCP are busy individuals. If the procedure for obtaining immunizations is not convenient, it will be difficult to achieve high rates of immunization at the institution. The IP may use formal and informal mechanisms to elicit feedback from HCP to determine reasons for poor compliance if this is a factor.
- Tie-in to other requirements: The immunization program can be tied in to the annual TST or symptom review for tuberculosis or to annual mandated educational programs, when the HCP is already required to be present.
- Subsidize the cost of vaccines: The HCP is more likely to consider immunization if there is no cost on the part of the employee. The IP can present cost analysis data to administration on the benefits of immunization versus working up outbreaks in the medical setting to justify the cost of the program.
- Monitor expectations and concerns: The IP is in an essential position to monitor concerns of HCP regarding the immunization program. Possible strategies for monitoring concerns and expectations include:
- Providing time for questions and answers on vaccinations at mandated educational programs. Ask HCP about their concerns regarding immunization.
- Setting up booths to promote the institution's immunization program, for example, during International Infection Prevention Week.
- Sending out surveys to HCP to elicit information on compliance with the immunization program, including reasons for and against compliance. Feed this information to administration and back to the HCP so that goals for improvement can be targeted.

Education

- The risk of disease, disability, and chronic disease: Annual infection prevention educational programs for HCP are already required according to the OSHA Bloodborne Pathogen Standard.[61,62] Thus, an opportunity to provide information is created for education on the risk of disease and disability that

may result from vaccine-preventable diseases at these sessions. The IP is in a critical position to include this information at these sessions.

- Vaccine efficacy and side effects: In addition to the mandated educational sessions for HCP discussed earlier, VIS can be distributed, vaccine updates can be provided, and the IP can include times in the sessions for HCP to ask questions about vaccine efficacy, safety, misconceptions, or other concerns. International Infection Prevention Week is an excellent opportunity each year in October for immunizations to be promoted. The IP can distribute pamphlets, set up displays, conduct educational sessions, or utilize other creative ideas for educating staff about vaccine-preventable diseases. In particular, it is advisable to promote influenza vaccination in HCP at this time.

Documentation

- Standardized recording of vaccine information: As mentioned, the NCVIA has requirements for specific information to be collected during the administration of vaccines. According to ACP, "Health care providers who administer vaccines covered by the NCVIA are required by law to record this information permanently for these vaccines in the recipient's medical record or in an office log or file." The information recorded should include the type of vaccine; dose, site, and route of administration; and name, address, and title of the person who gave the vaccine (required for vaccines covered by NCVIA).[66]Because this information is required for vaccines covered by NCVIA, standardization of the data that need to be recorded can be applied to all vaccines required at the institution. It may also be cost effective and efficient to utilize standardized information forms on vaccines for HCP. These forms may include but are not limited to the following: consent forms, VIS with all applicable information for each vaccine offered, screening forms for eliciting vaccine-preventable disease histories and serology results, exemption forms to be signed by physicians of HCP in instances where there is a medical contraindication to a vaccine that is required by hospital policy, and updates on vaccine information. The CDC has forms available through state and local health departments that meet the NCVIA criteria as information sheets.
- Monitoring compliance with policy: As mentioned, the failure of HCP to obtain recommended immunizations is a recurring problem. Individual institutions are thus faced with not only the responsibility of formulating policies regarding immunization of their employees, but also designing strategies to monitor compliance. This function can also be tied in to an employee database system. Possible strategies for monitoring compliance may include but not be limited to the following:
- Requiring vaccinations as a condition of employment and not allowing HCP to be hired if they do not comply with the policies.
- Sending notices to HCP to notify them that they have not received required vaccines.
- Disciplinary action for HCP who fail to receive required vaccines (unless there are medical contraindications).
- Periodic follow-up of persons who have declined vaccinations for medical reasons to evaluate whether the exemptions still apply.
- Relating compliance with performance appraisals and/or credentialing.
- Taking persons off the schedule if they do not comply with required immunizations within a designated time period.
- In those cases in which more extreme measures are utilized, it is important to consult with the Labor Relations Department to ensure that existing labor laws are not being violated.
- Developing an appropriate database for storage, accessibility, and review of information: Adequate monitoring and report functions are unlikely to be actively monitored, especially in large institutions,

without an appropriate and user-friendly database. Several software programs are available for maintaining immunization records of HCP. The cost of such programs can be justified when weighed against the inefficiency of not computerizing these data. When evaluating which program to purchase, consideration should be given to the amount of data entry required, including personnel time. Programs that have the capability to generate reminder notices, for example, for the second and third Hepatitis B dose or the second varicella vaccine dose, may be more desirable than those without such features.

- The database should be capable of storing the amount of information essential to the institution, be easily accessible, and have different options for review of information. For example, one may want to have information on compliance with Hepatitis B vaccination by job category, unit worked, year, etc.
- The program selected should also be able to accommodate updates in vaccine requirements that may not have been available at the time the system was originally purchased.

Conclusions

Widespread immunization programs are safe and cost-effective means of reducing the frequency of vaccine-preventable diseases. The absence of such programs in medical institutions can have devastating consequences because of the rapid transmission of vaccine-preventable diseases among HCP and their high-risk patients.

HCP should take advantage of opportunities to work together to ensure universal coverage for themselves and their peers. HCP should be encouraged to become familiar with specific immunization guidelines pertaining to themselves and should obtain and maintain adequate protection against vaccine-preventable diseases.

Future Trends

The use of vaccines is a cornerstone to an infection prevention and control program. Mandatory influenza immunization programs and addition of new vaccines into existing programs during economically challenging times are but two important issues that will be part of future planning and discussion.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Pregnant Healthcare Personnel

Author(s): Vicki Allen, MSN, RN, CIC, FAPIC
Director, Infection Prevention & Control

CaroMont Regional Medical Center
Gastonia, NC

Published: October 3, 2014

Abstract

Following Standard Precautions (i.e., consider all body fluids except sweat potentially infectious, and use personal protective equipment when exposure to blood or body fluids is anticipated), as recommended by the Centers for Disease Control and Prevention for all healthcare personnel, will protect pregnant healthcare personnel against most infectious agents to which they may be exposed. However, because some infectious agents can cause congenital syndromes in the fetus when primary infection is acquired during pregnancy, there are additional concerns in pregnant or potentially pregnant healthcare personnel. For practical purposes, immunologic function is normal during pregnancy, and an otherwise healthy woman is not considered to be an immunocompromised host. Pregnancy does not increase the risk of acquisition of infections and, for most infectious agents, clinical manifestations of infections are no more severe in pregnant women than in those who are not pregnant. In view of the routes of transmission and ubiquity of some infectious agents (e.g., cytomegalovirus), restricting pregnant women from caring for patients with potentially transmissible infections is considered only for patients infected with parvovirus B19 and for patients with respiratory syncytial virus infections who are receiving ribavirin aerosol. Because patients with vaccine-preventable diseases should be cared for by only immune healthcare personnel, it is especially important for women contemplating pregnancy to obtain the needed vaccines before conception. Similar to nonpregnant healthcare personnel, susceptible pregnant healthcare personnel should be restricted from contact with patients with rubeola, rubella, varicella, and smallpox. Much anxiety among pregnant healthcare personnel results from misinformation concerning epidemiology and transmission of infectious agents. The emphasis must be on education of all healthcare personnel of childbearing age, ideally before pregnancy, or at least as soon as pregnancy is diagnosed. It is important to note that the incidence of cytomegalovirus and parvovirus infection is not increased among healthcare personnel compared with other occupations, especially day care center staff and school teachers.

Key Concepts

- Consistent adherence of pregnant healthcare personnel to the practices of Standard Precautions, especially hand hygiene, will protect against most exposures to infectious agents of concern during pregnancy.
- Healthcare personnel should be immunized against vaccine-preventable diseases before conception. Once pregnancy occurs, most missed immunizations may still be provided but should occur only after consultation with the healthcare personnel's obstetrician. However, influenza vaccine is recommended for routine administration to pregnant women at any trimester if they will be pregnant during the influenza season, including the first trimester. Although live virus vaccines are not recommended during pregnancy, inadvertent administration of live attenuated virus vaccines (rubella, rubeola, varicella, smallpox) has not been associated with adverse outcomes as tracked in national registries.
- The exposure of nonimmunized pregnant healthcare personnel to varicella zoster virus presents a primary risk to the mother and fetus-neonate.
- Immunization during pregnancy and before conception provides benefit from the disease to the mother during pregnancy and benefit to the neonate by passive antibodies during the first 4 to 6 months of life.
- Reviewing the patient's immunization status before attempts to conceive is prudent.
- There are few healthcare exposures that will be associated with adverse outcomes for pregnant healthcare personnel or her fetus.

Background

Consistent adherence to Standard Precautions (i.e., consider all bodily fluids except sweat potentially infectious and use personal protective equipment [PPE] when exposure to blood and body fluid is anticipated), as recommended by the Centers for Disease Control and Prevention (CDC), provides pregnant healthcare personnel (HCP) and all HCP the optimal protection from exposure to infectious agents. Increased adherence to recommended precautions has been demonstrated for pregnant individuals when compared with nonpregnant individuals. Pregnant HCP have the additional concern of coming into contact with an infectious agent that may cause serious illness in the mother and may cause a congenital syndrome or some adverse pregnancy outcome. In general, maternal immune function is normal, but there is some decrease in cell-mediated immunity in the third trimester to viruses and pathogenic fungi.

HCP protection against vaccine-preventable diseases should be achieved by prepregnancy immunization. Immunization of pregnant HCP is indicated either to protect the mother, as is the case with the influenza vaccine, or to ensure the transfer of maternal antibody to the fetus, as with tetanus and influenza. The benefits of preventing disease during pregnancy clearly outweigh concerns about the safety of vaccines or immunoglobulins because no definable risks have been described.

Basic Principles

Patients who may be shedding certain infectious agents for which there is no vaccine may cause the pregnant HCP to be concerned regarding her safety and the safety of her fetus. These may include patients with cytomegalovirus (CMV), parvovirus B19, herpes simplex virus, syphilis, and rubeola, rubella, and varicella if not immune (Table 104-1). Although respiratory syncytial virus (RSV) infection

does not have an adverse effect on the pregnant woman, exposure to the ribavirin aerosol used for treatment of RSV is contraindicated during pregnancy based on theoretical, but unproven, adverse effects during pregnancy. It is essential that all HCP practice Standard Precautions to optimize their personal protection when caring for patients. If Standard Precautions are used, restriction of patient care responsibilities for pregnant HCP is rarely indicated. Despite this fact, one cannot underestimate the importance of recognizing the emotional aspects of pregnancy and the real potential for exposures to infectious agents. It may be prudent to consider alterations in patient care activities if fear of safety cannot be adequately addressed and adequate numbers of staff are available to allow such modifications. Such decisions are best made in collaboration with the healthcare management, the occupational health, and infection prevention and control departments, as well as the individual pregnant HCP. However, it is important to recognize that removing pregnant HCP from caring for the patient known to be infected with an agent of concern may result in re-assignment to a patient in whom an infection may be present but not yet identified, and adherence to Standard Precautions may be less likely. For example, 70 percent of children who attend day care centers may be shedding CMV and may be asymptomatic.

Table 104-1 Infectious Agents of Concern to the Pregnant Healthcare Personnel According to Risk of Transmission Associated With Delivery of Healthcare and Available Preventive Measures

Healthcare-associated Acquisition Possible and Prevented by Pre-exposure Vaccine	Healthcare-associated Acquisition Unlikely	Infection Prevention Precautions are the Only Preventive Measures	Postexposure Chemoprophylaxis Effective
Anthrax*	HSV	CMV	HIV
HAVa	Toxoplasmosis	HCV	*Neisseria meningitis*
HBV		Parvovirus B19	
Influenza		Tuberculosis	Syphilis
N. meningitis[†]			
Pertussis			
Rubella			
Rubeola			
Varicella			
Tetanus			
Diphtheria			
Smallpox			

*Rare.

[†]Considered for laboratory workers, for college freshmen living in dormitories, or during a community outbreak.

Pregnant HCP should have been immunized according to the schedule for adult immunization. Immunizations should include poliomyelitis; measles, mumps, rubella (MMR); varicella; tetanus; and diphtheria, or there should be a reliable history of having had the disease before becoming pregnant (Table 104-2). Pneumococcal vaccine should be administered preconceptually or during pregnancy in the second or third trimesters, especially if high-risk conditions are present (e.g., metabolic diseases such as diabetes mellitus or thyroid dysfunction; pulmonary, renal, or cardiac diseases; asthma; smoking; or functional or anatomic asplenia). Unfortunately, many adults do not have reliable records or memory of childhood vaccines or illnesses. In addition, HCP generally have access to information about vaccines and vaccine-preventable diseases but may not consider the benefits to themselves during pregnancy or to their newborn infant during the first 6 months of life. Healthcare institutions should mandate that HCP must complete the proper vaccine program as a condition of employment.

Table 104-2 Vaccination of Pregnant Women

Vaccine	General Recommendations for Use in Pregnant Women	Contraindicated During Pregnancy
Hepatitis A	Recommended if otherwise indicated	
Hepatitis B	Recommended in some circumstances	
Human papillomavirus (HPV)		Not recommended
Influenza inactivated	Recommended	
Influenza (LAIV)*		Contraindicated
Measles, mumps, rubella (MMR)		Contraindicated
Meningococcal conjugate (MCV4/MenACWY)	May be used if otherwise indicated	
Pneumococcal conjugate (PCV13)	Inadequate data for specific recommendation	
Pneumococcal polysaccharide (PPSV23)	Inadequate data for specific recommendation	
Polio (inactivated poliovirus vaccine [IPV])	May be used if needed	
Tetanus and diphtheria (Td)	Should be used if otherwise indicated	
Tetanus, diphtheria, and pertussis (Tdap)[†‡]	Recommended	
Varicella		Contraindicated
Zoster (shingles)		Contraindicated
Travel and Other Vaccines		
Anthrax	High risk of exposure: May be used	Low risk of exposure: Not recommended
Bacille Calmette-Guérin (BCG)		Contraindicated

Japanese encephalitis	Inadequate data for specific recommendation	
Meningococcal polysaccharide (MPSV4)	May be used if otherwise indicated	
Rabies	May be used if otherwise indicated	
Typhoid	Inadequate data for specific recommendation	
Vaccinia (smallpox)	Postexposure: recommended	Preexposure: contraindicated
Yellow fever	May be used if benefit outweighs risk	

*LAIV: Do not administer LAIV to pregnant women (Centers for Disease Control and Prevention [CDC]. *Guidelines for Vaccinating Pregnant Women.*CDC website. 2013. Available at:**http://www.cdc.gov/vaccines/pubs/preg-guide.htm**).

†For women not previously vaccinated with Tdap. If Tdap is not administered during pregnancy, Tdap should be administered immediately postpartum.

‡Wound management: If a Td booster is indicated for a pregnant HCP, healthcare providers should administer Tdap.

From Centers for Disease Control and Prevention. Updated recommendations for use of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap) in pregnant women – Advisory Committee on Immunization Practices (ACIP), 2012. *MMWR Morb Mortal Wkly Rep*2013;62 (No. 7):131–135.

No evidence exists for risk from vaccinating pregnant women with inactivated vaccines or toxoids. In addition, pregnancy registries have demonstrated no harmful fetal effects when polio, rubella, varicella, and smallpox vaccines have been administered inadvertently to women who did not know they were pregnant. Benefits of maternal vaccination include protecting the mother from disease and protecting the neonate from disease for the first 3 to 6 months of life by passively transferred antibody via the umbilical cord.

DISEASE AND PREGNANT HEALTHCARE PERSONNEL

There are numerous questions regarding occupational exposures to infectious agents (Table 104-3). This table lists many of the infectious agents pregnant HCP may encounter during employment or in nonoccupational activities.

Table 104-3 Pregnant Healthcare Worker: Guide to Management of Occupational Exposure

Agent	In-hospital Source	Potential Effect on the Fetus	Rate of Perinatal Transmission	Maternal Screening	Prevention

Anthrax				History of exposure	Pre-pregnancy vaccination; vaccine not licensed for use in pregnancy Postexposure chemoprophylaxis with ciprofloxacin or amoxicillin if source
CMV	Urine, blood, semen, vaginal secretion, immunosuppressed transplant, dialysis, day care	Classic cytomegalic inclusion disease (5 to 10 percent)* Hearing loss (10 to 15 percent)	Primary infection (25 to 50 percent) Recurrent infants (52 percent) Symptomatic (<5 to 15 percent)	Routine screening not recommended; antibody is incompletely protective	Efficacy of CMV immune globulin not established No vaccine available Standard Precautions
HAV	Feces (most common), blood (rare)	No fetal transmission described; transmission may occur at the time of delivery if women still in the infectious phase and cause hepatitis	None	Routine screening not recommended	Vaccine is a killed viral vaccine and can safely be used in pregnancy. Contact Precautions during acute phase. The safety of Hepatitis A vaccination during pregnancy has not been determined; however, because the vaccine is produced from inactivated HAV, the theoretical risk to the developing fetus is expected to be low. The risk associated with vaccination, however, should be weighed against the risk for Hepatitis A in women who might be at high risk for exposure to HAV.
HBV	Blood, bodily fluids, vaginal secretions, semen	Hepatitis, early onset hepatocellular carcinoma	HbsAg + 10 percent HbeAg + 90 percent	Routine HBsAg testing advised	HBV vaccine during pregnancy Neonate: HBIG plus vaccine at birth Standard Precautions
HCV	Blood, sexual	Hepatitis	5 percent (0 to 25 percent)	Routine screening not recommended	No vaccine or immunoglobulin available; postexposure treatment with antiviral agents investigational Standard Precautions

HSV	Vesicular fluid, oropharyngeal and vaginal secretions	Sepsis, encephalitis, meningitis, mucocutaneous lesions, congenital malformation (rare)	Primary genital (33 to 50 percent) Recurrent genital (1 to 2 percent)	Antibody testing minimally useful genital inspection for lesions if in labor	Chemoprophylaxis at 36 weeks decreases shedding Standard Precautions
HIV	Blood, bodily fluids, vaginal secretions, semen	No congenital syndrome. If fetus infected, AIDS in 2 to 4 years.	Depends on HIV viral titer If titer <1,000 virus; rate, 2 percent If titer ≥10,000; rate up to 25 percent	Routine maternal screening advised. If exposed, testing at 3, 6, and 12 months	Antiretroviral chemoprophylaxis available for exposures, postnatal chemoprophylaxis for HIV+ mothers and their infants Standard Precautions
Influenza	Sneezing and coughing, respiratory tract secretions	No congenital syndrome: Influenza in mother could cause hypoxia in fetus	Rare	None	TIV for all pregnant women during influenza season to decrease risk of hospitalization for cardiopulmonary complications in mother Droplet Precautions
Measles (rubeola)	Respiratory secretion coughing	Prematurity spontaneous abortion no congenital syndrome	Rare	Antibody test	Vaccine Airborne Precautions
N. meningitidis	Respiratory secretion of untreated patients or those who have received antimicrobials for <24 hours	Sepsis No congenital syndrome	Unknown	None	Chemoprophylaxis with ceftriaxone or azithromycin Vaccine if indicated for outbreak control Standard Precautions, especially mask, face protection for all intubations
Parvovirus B19	Respiratory secretion, blood, immunocompromised patients	Fetal hydrops, stillbirth, no congenital syndrome	Approximately 25 percent; fetal death <10 percent	No routine screening. B19 DNA can be detected in serum, leukocytes, respiratory secretions, urine, tissue specimens	No vaccine. Defer care of immunocompromised patients with chronic anemia when possible Droplet Precautions

Rubella	Respiratory secretions	Congenital syndrome	90 percent in first trimester 40 to 50 percent overall	Routine rubella IgG testing in pregnancy Preconception screening recommended	Vaccine No congenital rubella syndrome described for vaccine Droplet Precautions; Contact Precautions; for points with congenital rubella
Smallpox (vaccinia)	Respiratory secretions, contents of pustular-vesicular lesions	Fetal vaccinia, premature delivery, spontaneous abortion, and perinatal death		History of successful vaccination within previous 5 years	Pre-event contraindicated during pregnancy. Vaccine and vaccinia immunoglobulin after exposure; pre-exposure; pre-exposure vaccine only if smallpox present in the community and exposure to patients with smallpox likely. Airborne infection isolation plus Contact Precautions.
Syphilis	Blood, lesion, fluid, amniotic fluid	Congenital syndrome	Variable 10 to 90 percent depends on stage of maternal disease and trimester of the infection	VDRL RPR FTA ABS	Postexposure prophylaxis with penicillin Standard Precautions gloves until 24 h of effective therapy completed for infants with congenital syphilis and all patients with skin and mucous membrane lesions
Tuberculosis	Sputum, skin lesions	Neonatal tuberculosis; liver most frequently infected	Rare	Tuberculin skin test or BAMT Chest radiograph	Varies with TST reaction size and chest radiograph result Airborne Precautions
Varicella zoster	Droplet or airborne spread of vesicle fluid or secretions of the respiratory tract (scabs are not infective)	Malformations (skin, limb, CNS, eye); chickenpox	Total 25 percent: congenital syndrome (0 to 4 percent)	Antibody	Vaccine; VZIG within 96 hours exposure if susceptible; Airborne and Contact Precautions

TIV, trivalent inactivated.

*Congenital syndrome: varying combinations of jaundice, hepatosplenomegaly, microcephaly, thrombocytopenia, anemia, retinopathy, and skin and bone lesions.

†Live virus vaccine given before or after pregnancy.

Counsel pregnant women and women of childbearing age regarding the risk of transmission of infectious diseases (e.g., CMV, hepatitis, HIV, parvovirus, rubella) that, if acquired during pregnancy, may have adverse effects on the fetus, whether the infection is acquired in nonoccupational or occupational environments. Information regarding occupational exposure to infectious agents including preventive measures such as Standard and Transmission-based Precautions is included in Table 104-3 and should be accessible and provided to pregnant HCP. It is not necessary to routinely exclude women strictly on the basis of their pregnancy, or intent to become pregnant, from the care of patients with particular infections that have potential to harm the fetus.

CYTOMEGALOVIRUS

No vaccine is available for CMV and consistent adherence to Standard Precautions is the only preventive measure. The clinical entity, cytomegalic inclusion disease, was described in 1950. This generalized congenital infection was associated with cytomegalic cells, and typical intranuclear inclusions were found in multiple organs. The virus was grown on cultured human cells in 1956 and is now recognized as the most frequent congenitally and perinatally acquired viral disease known in humans. It is the single most important infectious cause of mental retardation and congenital deafness in the United States.

CMV infection is restricted to humans. The virus is widespread, and infection is more common than disease. By serology, 80 to 90 percent of individuals are exposed during their lifetime. Seropositivity among women in the reproductive years (15 to 35) is approximately 50 percent in middle and upper socioeconomic groups and 90 percent in the lower socioeconomic groups.

CMV is transmitted most frequently by sexual contact or by direct contact with infected urine, saliva, semen, vaginal secretions, or breast milk. Major risks for primary infections among seronegative women include the following:

1. Age <25 years
2. Multiple sexual partners
3. Exposure to young children (especially those who attend day care) at home and in the work place; for example, day care centers and schools

The rate of seroconversion in seronegative women is 1 to 3 percent per year, but is as high as 10 to 20 percent in women who work in day care centers, and approaches 50 percent when an infected child

younger than 2 years of age is present in the home. HCP do not have an increased risk of acquisition of CMV infection.

CMV crosses the placenta with relative ease, and congenital infection occurs in 1 to 2 percent of all pregnancies. Perinatal infections are acquired by exposure to the mother's infected genitourinary tract and by ingestion of breast milk from an infected mother. Organ transplants, blood transfusions, and dialysis centers are other sources of infections. The spread of CMV among the general population is facilitated by asymptomatic primary and recurrent infections, multiple sites of excretion, prolonged and intermittent excretion, and excretion of virus despite the presence of specific immunity. Asymptomatic transmission further supports the need for adherence to Standard Precautions among all HCP when in contact with all patients.

CMV infections are considered congenital if virus excretion or serological evidence (CMV immunoglobulin M [IgM]) is found in the infant within the first 2 weeks of life. Transmission of CMV to the fetus can occur during primary and recurrent infections despite maternal antibody. Although maternal immunity is not completely protective, it plays a major role in reducing the virulence of infection and the severity of the clinical manifestations in the fetus or newborn. The frequency of congenitally infected infants among seropositive women is 2 to 3 percent, whereas primary maternal infections carry an overall risk to the fetus of 25 to 50 percent. Ninety percent of congenitally infected infants will shed virus at birth and do so for 6 years or longer, even in the presence of antibody.

Congenital infections range from asymptomatic and unrecognized (90 percent) to multiple organ system involvement that is sometime incompatible with life in 10 percent or less. Most of the asymptomatic infections do not endanger life, but 10 to 15 percent of these infants are at risk for long-term sequelae, such as progressive sensorineural hearing loss, chorioretinitis, and dental abnormalities.

Approximately 5 to 10 percent of congenitally infected infants will have significant stigmata of infection at birth. Approximately half will have classic cytomegalic inclusion disease, and half will have atypical involvement. All infants will excrete CMV at birth. The rate of mortality infections in infants in this group is 20 to 30 percent. Children are most severely affected as a result of primary maternal infections that occur early in pregnancy.

Acquisition of CMV in the neonatal period is common, but the consequences of perinatally acquired infections are considerably less serious than for congenital infections. Incubation time from exposure to infection (asymptomatic or symptomatic) is 4 to 12 weeks, and greater than 50 percent will be asymptomatic. Blood transfusion was the source of most perinatal CMV infections before there were recommendations for using specially treated blood in low-birth-weight neonates.

Preventing primary infections in seronegative women during pregnancy would be valuable. Because CMV is ubiquitous, there is no treatment available, and the incidence of congenital CMV syndrome with its devastating neurologic effects is rare. Serologic screening is not offered to women routinely. Although transfer to a presumed lower-risk patient care unit is an appealing option, it is difficult to identify such an area in most acute care hospitals or healthcare institutions that care for toddlers.

HEPATITIS A VIRUS

Hepatitis A virus (HAV) infection used to be one of the most frequently reported vaccine-preventable diseases. However, with more widespread use of HAV vaccine in populations defined by higher disease prevalence rates, there has been a 97 percent decrease in the incidence of this infection in the United States. HAV replicates in the liver, is excreted in the bile, and is shed in the stool. Peak infectivity occurs during the 2 weeks before the onset of jaundice or elevation of hepatic transaminases, when the

viral concentration in the stool is greatest. Chronic shedding does not occur, and viremia is present only soon after infection and persists through the time of hepatic transaminase elevation.

Transmission is primarily from exposure to contaminated feces, but blood can be a source for a short period of time. Maternal HAV transmission to the fetus has not been established. HAV infection during pregnancy can cause an increased risk of severe systemic infections, spontaneous abortion, and preterm delivery. Hepatitis A is an inactivated vaccine and, similar to Hepatitis B vaccines, is recommended if another high-risk condition or other indication is present.

HEPATITIS B VIRUS

Hepatitis B virus (HBV) infection during pregnancy can result in severe disease for the mother, fetal loss, or chronic infection of the neonate if born alive. The prolonged HBV viremia may persist from weeks to months and provides adequate time for vertical transmission. Chronic HBV infections occur in 1 to 5 percent of adults with acute HBV infection. However, in neonates, as many as 90 percent will manifest chronic infection; 50 percent of infected infants and 20 percent of infected young children will develop chronic infection. This demonstrates the importance of an effective HBV immunization program in the maternal and child health areas within healthcare facilities.

Pregnancy is not a contraindication to vaccination. Limited data suggest that developing fetuses are not at risk for adverse events when Hepatitis B vaccine is administered to pregnant women. Available vaccines contain noninfectious Hepatitis B surface antigen (HBsAg) and should cause no risk of infection to the fetus.

Postexposure Prophylaxis for HBV During Pregnancy

No apparent risk exists for adverse effects to developing fetuses when Hepatitis B vaccine is administered to pregnant women (CDC, unpublished data, 1990). The vaccine contains noninfectious HBsAg particles and should pose no risk to the fetus. HBV infection during pregnancy might result in severe disease for the mother and chronic infection for the newborn. Therefore, neither pregnancy nor lactation should be considered a contraindication to vaccination of women. Hepatitis B immunoglobulin (HBIG) is not contraindicated for pregnant or lactating women.

HBV vaccine should be administered in pregnancy when a high-risk indication is present. See **97. Viral Hepatitis**, and **103 Immunization of Healthcare Personnel**, for all indications for HBV vaccine.

All pregnant women should be screened for HBsAg early in pregnancy and later in pregnancy if indicated by participation in high-risk activities such as multiple sexual partners, illicit drug abuse, and acquisition of another sexually transmitted infection.

Previously unvaccinated women who are HBsAg-negative should receive the HBV vaccine series (0, 1, 6 to 12 months). Infants of HBsAg-negative mothers should receive HBV vaccine at birth, whereas infants of HBsAg-positive women should receive HBIG in addition to the first dose of vaccine as soon as possible and ideally within 12 hours of birth.

HEPATITIS C VIRUS

Hepatitis C virus (HCV) may be transmitted sexually, by exposure to blood via transfusion, sharing needles for intravenous drug use, percutaneous injury, and, rarely, perinatal exposure. Transmission via blood transfusion is prevented by screening blood donors for laboratory evidence of HCV infection. No vaccine and no effective therapy during pregnancy or the postnatal period exist at the current time. In fact, it has not been determined if postexposure prophylaxis (PEP) with antiviral agents is beneficial,

because it may inhibit the natural protective immune response. Therefore, preventing occupational exposure is by avoiding percutaneous blood exposures via the use of safety devices and wearing gloves.

The epidemiology of HCV resembles HBV. The prevalence of HCV in the United States is 1.5 percent, but is higher in African Americans and inner city pregnant women. Injectable drug use is the major mode of transmission. Both sexual and maternal-fetal transmission have been described, but with low frequencies. Studies of pregnant women who are HCV seropositive suggest that injectable drug use and sexual contact with injectable drug users are the major risk factors responsible for HCV infection in women. The risk of developing chronic HCV infection without evidence of active liver disease is higher than for HBV infection, approaching 75 percent. The incubation period is 15 to 160 days with a peak at 50 days.

The maternal-fetal transmission risk in an HCV seropositive mother is 10 percent, and infection rates can be correlated with the level of maternal viremia. Studies have shown that acute HCV infection in the first and second trimesters causes fetal hepatic injury, whereas acute HCV infection in the third trimester results in serum transaminase elevations without jaundice or evidence of hepatitis in the neonate.

HERPES SIMPLEX VIRUS

No vaccine is currently available for herpes simplex virus (HSV), and prevention is by adhering to Standard Precautions. Healthcare-associated HSV infection is most likely to manifest as a herpetic whitlow, is prevented by the use of gloves for contact with mucous membranes, and is unlikely to affect the genital tract or the fetus.

There are two major types of HSV: HSV-1 and HSV-2, with multiple strains of each. HSV-1 and HSV-2 share approximately 50 percent of their DNA sequences. Viral replication occurs in the cell nucleus with production of virus within 10 to 14 hours after infection.

Transmission of HSV occurs by intimate contact, such as oral-oral, oral-genital, and genital-genital contact. Transmission by fomites contaminated by body fluids has been documented. Humans are the sole natural host for HSV, and 55 to 90 percent of the general population has antibodies to HSV-1, HSV-2, or both. In the United States, serologic evidence of infection with HSV-2 ranges from less than 1 percent in those aged 15 years or younger to greater than 25 percent in those aged 30 years. Two-thirds of individuals who are seropositive for HSV-2 report no clinical history or exposure to another infected person.

HUMAN IMMUNODEFICIENCY VIRUS

No vaccine is currently available for HIV; however, chemoprophylaxis is available for occupational exposures. Handling PEP is covered in **101. Occupational Exposure to Bloodborne Pathogens**.

HIV infection causes destruction of the immune system, particularly CD4 cells, and can result in the clinical acquired immunodeficiency syndrome (AIDS). The risk factors for women or their sexual partners for acquiring HIV infection are as follows:

- Illicit drug use; especially injectable drug use
- Current or previous multiple sexual partners
- Trading sex for drugs
- Transfusion of blood products before 1985

- Bisexual activity
- Residence in or origin from HIV-endemic areas
- Symptoms of HIV-related illnesses
- History of current sexually transmitted infection

In addition to those listed, risk factors for acquiring HIV are as follows:

- Maternal-fetal transmission
- Transplantation of organs
- Artificial insemination
- Breastfeeding

Maternal-fetal transmission may occur transplacentally in utero or perinatally. The rate of transmission is determined by the viral titer in the mother. Studies in the United States have indicated that the transmission rate in nontreated women is 25 percent, whereas those receiving antiretroviral chemotherapy have a transmission rate of 1 to 8 percent. In Africa, breastfeeding appears to account for 7 to 22 percent of all HIV transmission. When safer forms of nutrition are available, breastfeeding is contraindicated in HIV-infected mothers. Management of the HIV-infected pregnant woman includes antiretroviral therapy during pregnancy, during labor, and after delivery for the neonate. Maternal antiretroviral therapy is continued after delivery.

Despite the increasing use of safety devices, occupational exposures will occur and the seroconversion after percutaneous exposure is 0.3 percent, whereas seroconversion after mucous membrane, nonintact skin exposure is 0.09 percent. Risk of percutaneous transmission is increased with hollow-bore needles and when an increased volume of blood is injected. Consistent adherence to Standard Precautions and use of needleless systems and other safety needles will decrease the risk of exposure.

PEP for Pregnant HCP

If the exposed person is pregnant, the evaluation of risk of infection and need for PEP should be approached as with any other person who has had an HIV exposure. However, the decision to use any antiretroviral drug during pregnancy should involve discussion between the HCP and her healthcare provider(s) regarding the potential benefits and risks to her and her fetus. Certain drugs should be avoided in pregnant women—another reason for involving the pregnant HCP healthcare provider—and, therefore, expert consultation for HIV PEP is advised for known or suspected pregnancy in the exposed person.

HUMAN PAPILLOMAVIRUS

Human papillomavirus (HPV) vaccines are not recommended for use in pregnant women. If a woman is found to be pregnant after initiating the vaccination series, the remainder of the three-dose series should be delayed until completion of pregnancy.

INFLUENZA

Influenza is an acute respiratory illness characterized by myalgias, laryngotracheal bronchitis, fever with a nonproductive cough, and acute and chronic debilitation. In the United States, seasonal epidemics of influenza typically occur during October to March. During 30 seasons from the 1976 to 1977 season through the 2005 to 2006 season, estimated influenza-associated deaths ranged from 3,000 to 49,000 annually. Increased severity of influenza among pregnant women was reported during the pandemics of

1918 to 1919, 1957 to 1958, and 2009 to 2010. Pregnant women are at increased risk for severe illness from influenza because of physiologic changes during pregnancy.

Influenza is transmitted in most instances via respiratory secretions from sneezing and coughing (e.g., droplet transmission). Although airborne transmission via small droplet nuclei has been documented (rarely) under certain conditions, large droplet transmission within 3 feet is the primary means of transmission. Influenza vaccination is the best method of preventing influenza and its complications. The Advisory Committee on Immunization Practices (ACIP) recommends routine annual influenza vaccination for all persons aged ≥6 months that do not have contraindications. Recommendations pertaining to the use of specific vaccines and populations can be found in the annual *Morbidity and Mortality Weekly Report*on prevention and control of seasonal influenza with vaccines.

It is important to note that when there are shortages in vaccine supply, as in the 2004 to 2005 season, vaccine is recommended only for those who are pregnant, those with high-risk conditions, all persons age 65 years or greater (instead of 50 years), HCP with direct face-to-face or hands-on contact with patients, and close household contacts or out-of-home caregivers of infants younger than 6 months of age.

Influenza is a common viral disease, and pregnant HCP can be a vector to patients and become infected with the influenza virus herself. The risk of hospitalization for a pregnant woman with influenza during the second and third trimesters is equivalent to that of nonpregnant individuals with underlying cardiopulmonary disease. All HCP should be immunized with influenza vaccine on a yearly basis to protect themselves, their patients, and their families. Currently, the live attenuated influenza vaccine is not recommended during pregnancy.

MEASLES, MUMPS, AND RUBELLA

A highly effective vaccine exists for measles, and all HCP should have received immunization before having patient contact. The measles-mumps-rubella (MMR) vaccine combines measles, mumps, and rubella vaccines and is highly effective.

The MMR vaccine and its component vaccines should not be administered to women known to be pregnant. Because a risk to the fetus from administration of these live virus vaccines cannot be excluded for theoretical reasons, women should be counseled to avoid becoming pregnant for 28 days after vaccinations with measles or mumps vaccines or MMR or other rubella-containing vaccines.

All women of childbearing age, including those who grew up outside the United States in areas where routine rubella vaccination might not occur, should be vaccinated with one dose of MMR vaccine or have other acceptable evidence of rubella immunity. Nonpregnant women of childbearing age who do not have documentation of rubella vaccination, serologic evidence of rubella immunity, or laboratory confirmation of rubella disease should be vaccinated with MMR vaccine. Birth before 1957 is not acceptable evidence of rubella immunity for women who could become pregnant.

Measles occurs primarily in late winter and spring. Transmission is primarily person-to-person via droplet and airborne routes. Measles is highly contagious, with a secondary household attack rate of 90 percent. Death is usually from pneumonia or acute encephalitis and occurs in 1 to 2 of 1,000 cases, which constitutes the main rationale for universal immunization. MMR is not indicated during pregnancy because it contains three live attenuated vaccines, but it should be given postpartum to the nonimmune woman. This demonstrates the importance of ensuring that an effective postpartum immunization program exists in the maternal and child health areas in healthcare facilities.

Rubella (German measles) is a mild, exanthematous viral infection that primarily affects children. Except for rubella infecting pregnant women, there are practically no complications.

The disease is transmitted by respiratory secretions, and the incubation period is 10 to 14 days. The patient infected with rubella should be placed on Droplet Precautions. The maculopapular rash spreads from the thorax and face to the extremities. A low-grade fever and posterior auricular lymphadenopathy are frequently present. The viremia can persist for as long as 46 days after initial infection. Ensuring immunity of HCP in obstetrical clinics and offices is especially important because transmission of this virus from HCP to pregnant women in these settings has been associated with congenital rubella syndrome.

The presentation of the infection in the newborn may range from no symptoms to the multi-organ system involvement that characterizes the congenital rubella syndrome. The syndrome includes a growth-restricted infant who has a chronic infection with this virus. The gestational age of the infection determines the severity of the syndrome. Maternal infection at less than 8 weeks causes 85 percent fetal infection rate, whereas maternal infection at 20 weeks causes a fetal infection rate of 10 percent. Babies born with congenital rubella should be placed on Contact Precautions.

The signs of infection may be so nonspecific that rubella immunoglobin (Ig) G serology is necessary to confirm infection. All pregnant women should be screened for rubella IgG at a preconception visit or early in pregnancy. If the person is rubella nonimmune, the appropriate time to vaccinate the patient is postpartum with MMR vaccine.

PARVOVIRUS B19

Parvovirus B19 was discovered in 1975 and is the causative agent of erythema infectiosum (also known as fifth disease), a common childhood illness. This agent is of concern to pregnant HCP because B19 can cause infection of fetal red blood cell precursors and lead to severe anemia and high-output cardiac failure in the fetus, hydrops fetalis, and fetal death. Parvovirus B19 infection of patients with hemolytic anemia (e.g., sickle cell disease) can be associated with a transient aplastic crisis and with a prolonged anemia in immunodeficient hosts (e.g., HIV-infected patients, patients receiving chemotherapy).

Respiratory secretions transmit parvovirus B19 during close contact. Patients infected with parvovirus B19 should be placed on Droplet Precautions. However, the period of infectivity is over by the time the rash of fifth disease has occurred; these patients need not be placed on Droplet Precautions. Transmission will occur in 10 to 60 percent of school contacts. The viral infection is characterized by a facial rash that resembles a slapped cheek and a reticular pattern of rash on the arms. The virus may persist for a prolonged period of time in immunocompromised patients, and the duration of infectivity is not known. However, transmission of infection may occur as long as the blood polymerase chain reaction (PCR) remains positive.

B19 infection can be diagnosed by B19 IgM serology after the third day of the rash and is present for 30 to 60 days. B19 IgG is present within 7 days and remains detectable for years. PCR may be used to detect parvovirus B19 in the blood.

The major effect of B19 infection is fetal hydrops and death. The likelihood of fetal death after maternal B19 infection is less than 10 percent. Diagnostic ultrasound is the most widely available test to detect fetal hydrops; this may resolve spontaneously or may be treated via intrauterine digoxin. Thus, fetal infection with parvovirus B19 is not an indication for interruption of pregnancy.

Parvovirus B19 infection in a pregnant woman represents a risk to the unborn child. It therefore makes sense to establish a woman's immunological status early in pregnancy. Five percent of infections in the first 20 weeks of pregnancy will result in fetal death. These are often early miscarriages.

PERTUSSIS

Pertussis is an acute respiratory infection caused by *Bordetella pertussis*. The organism produces multiple toxins that damage respiratory epithelium and can have systemic effects including the promotion of lymphocytosis.

The incubation period for pertussis is 7 to 10 days (range: 5 to 21 days). Classic pertussis is characterized by three phases: catarrhal, paroxysmal, and convalescent. The catarrhal phase lasts 1 to 2 weeks and consists of infection of the conjunctiva, frequent sneezing, a watery nasal discharge, and frequent cough. The cough suggesting tracheal irritation is short, hacking, isolated, and present equally day or night. Fever is uncommon during any phase.

The paroxysmal phase lasts 4 to 6 weeks. During this phase, the patient has intermittent periods of intense coughing (paroxysmal) with periods when the patient lives well. The paroxysms are characterized by severe spasms of coughing, choking, post-tussive, and an inspiratory whoop. Adults with pertussis make repeated visits for medical care and miss work and school.

Pertussis is transmitted from person to person via large respiratory droplets generated by coughing or sneezing. Reports suggest pertussis could be recovered from dry mucus up to 3 days. Persons with pertussis are highly infectious: Attack rates among exposed nonimmune households are as high as 80 to 90 percent. The most infectious periods are the catarrhal and early paroxysmal phases. Patients can remain infectious for 6 weeks or more.

The source of pertussis for infected pregnant women has not been systematically studied. In one study of 111 adults aged 18 to 29 years, the source was a person in the household (25 percent), at work or school (25 percent), a relative (7 percent), a friend (5 percent), and unknown (37 percent). In another study of adults aged 30 to 39 years, the source was a person in the household (44 percent), at school or work (17 percent), a relative (4 percent), a friend (5 percent), and unknown (31 percent).

Although the mortality and morbidity in pregnant women are similar to disease in the nonpregnant woman, the disease in the infant can be severe. Infants aged younger than 12 months and especially age younger than 3 months are most likely to have severe pertussis, require hospitalization, and have respiratory and other complications of pertussis. Most deaths due to pertussis occur in infants less than 2 months of age.

Tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) vaccine is recommended before pregnancy, during pregnancy, or immediately postpartum. The value of antepartum administration is to protect the mother from disease, but also to provide the neonate with passive antibodies for protection from disease until the infant's active immunity occurs. Infant immunization with DTaP (the childhood form of the pertussis vaccine) occurs at 2, 4, and 6 months of life, and the infant is not protected until 6 months of life.

Pertussis is another serious infectious disease that pregnant HCP are susceptible to and can transmit to patients. Only 2 percent of adults in the United States are protected against pertussis so there is a high probability that most HCP are not only susceptible to infection but also can transmit pertussis to their patients, family, or neonate.

In October 2011, in an effort to reduce the burden of pertussis in infants, ACIP recommended that unvaccinated pregnant women receive a dose of Tdap. Vaccination of women with Tdap during pregnancy is expected to provide some protection to infants from pertussis until they are old enough to be vaccinated themselves. Tdap given to pregnant women will stimulate the development of maternal antipertussis antibodies, which will pass through the placenta, likely providing the newborn with protection against pertussis in early life, and will protect the mother from pertussis around the time of delivery, making her less likely to become infected and transmit pertussis to her infant. The 2011 Tdap recommendation did not call for vaccinating pregnant women previously vaccinated with Tdap. On October 24, 2012, ACIP voted to recommend use of Tdap during every pregnancy.

Pregnant Women Due for Tetanus Booster

If a tetanus and diphtheria booster vaccination is indicated during pregnancy (i.e., .10 years since previous Td), then Tdap should be administered. Optimal timing is between 27 and 36 weeks' gestation to maximize the maternal antibody response and passive antibody transfer to the infant.

Wound Management for Pregnant Women

As part of standard wound management to prevent tetanus, a tetanus toxoid-containing vaccine might be recommended for wound management in a pregnant woman if ≥5 years have elapsed since the previous Td booster. If a Td booster is recommended for a pregnant woman, healthcare providers should administer Tdap.

Pregnant Women with Unknown or Incomplete Tetanus Vaccination

To ensure protection against maternal and neonatal tetanus, pregnant women who never have been vaccinated against tetanus should receive three vaccinations containing tetanus and reduced diphtheria toxoids. The recommended schedule is 0, 4 weeks, and 6 through 12 months. Tdap should replace one dose of Td, preferably between 27 and 36 weeks' gestation to maximize the maternal antibody response and passive antibody transfer to the infant.

SMALLPOX (VACCINIA)

Because of the limited risk but severe consequences of fetal infection, smallpox vaccine should not be administered in a pre-event setting to pregnant women or to women who are trying to become pregnant.

Smallpox is a severe, disseminated viral disease with a characteristic vesicular-pustular rash distributed over the extremities, palms, and soles. It is caused by variola minor and variola major viruses, and was associated with mortality rates as high as 30 percent. The last naturally acquired infection occurred in Somalia in 1977, and global eradication was declared in 1980. Routine vaccination was stopped in the United States in 1972. Smallpox caused excessive mortality in pregnant women: a 33 percent case fatality rate, with 27 percent among vaccinated pregnant women and 61 percent among unvaccinated pregnant women. Excessive rates of premature delivery, spontaneous abortion, and perinatal death were associated with smallpox during pregnancy. Although vaccinia virus used for smallpox vaccination is not teratogenic, fetal vaccinia was a rare complication of vaccination of the pregnant woman, with less than 30 cases reported in the world's literature from 1932 to 1978. Estimated incidence has been 1 of 10,000 exposed, but no cases were observed when approximately 173,000 pregnant women were vaccinated in New York City in 1947.

A targeted smallpox vaccination program (~700,000 military personnel and 40,000 civilians who would serve as members of emergency response teams) was initiated in the United States in December 2002

and January 2003 in response to the perceived threat of smallpox as a bioweapon. Because of potential adverse effects of vaccinia on the fetus, pregnancy was considered a contraindication to receiving the vaccine in this program, and all women in the childbearing age group were screened with a questionnaire and counseled to prevent fetal exposure to vaccinia. As of June 2004, 236 vaccinia-exposed pregnancies were reported to the National Smallpox Vaccine in Pregnancy Registry. Analysis available in June 2004 revealed the following: (1) pregnancy occurred less frequently in vaccinia-exposed women compared with the expected rate of pregnancy in unscreened women of childbearing age; (2) no excess adverse effects were observed in the vaccinia-exposed pregnancy; and (3) 75 percent of the women in the registry were exposed to vaccinia before a pregnancy test could have been positive. Thus, the screening program used was effective in preventing fetal exposure to vaccinia and should be included in all pre-event smallpox vaccination programs. However, if inadvertent vaccination during pregnancy does occur, adverse outcome due to exposure to vaccinia virus is unlikely.

SYPHILIS

Syphilis is a complex, chronic sexually transmitted infection that can have profound effects on pregnancy. It is characterized by a 3-week incubation stage; a primary stage with a single-cutaneous lesion and regional lymphadenopathy; a secondary stage with mucocutaneous lesions, lymphadenopathy, and spirochetemia; a latent period of variable length; and, finally, a progression to serious systemic manifestations. It is acquired by the fetus transplacentally at any time during pregnancy and can be treated successfully with penicillin.

Syphilis can be acquired by intimate sexual contact and direct, unprotected contact with primary or secondary lesions on mucous membranes or skin. Healthcare-associated acquisition of syphilis is highly unlikely because, according to Standard Precautions, HCP would be wearing gloves for contact with any suspicious lesions or blood of patients with suspected syphilis. If a significant exposure does occur (e.g., percutaneous or mucocutaneous exposure to blood or fluid in lesions before or within the first 24 hours of treatment), PEP should be initiated with penicillin as soon as possible. Fetal risks for infection are directly proportional to the degree of maternal spirochetemia and the duration of the untreated maternal infection. The highest rates of congenital syphilis occur in women with secondary syphilis. Fifty percent of infants born to women with untreated primary or secondary syphilis will have congenital infection at birth. The remainder will be infected at delivery. Only 6 to 14 percent of fetuses of women in the late latent stage will be affected.

Serologic tests for antibody production allow the clinician to make the diagnosis. The nontreponemal test, rapid plasma reagin (RPR) test, or Venereal Disease Research Laboratory (VDRL) test can be used to screen for disease and follow response to therapy. Treponemal tests are used for confirmation if the VDRL or RPR is positive. Common treponemal tests are the microhemagglutination assay for antibodies (MHA-TP) or the fluorescent treponemal antibody-absorption (FTA-ABS).

The efficacy of the currently recommended treatment regimens for adult or antepartum early syphilis is 98 percent; most treatment failures are reinfections. Penicillin is the drug of choice during pregnancy. Treatment failures can occur with penicillin treatment but are more likely to occur if treatment is later in pregnancy, if a drug other than penicillin is used, in the presence of higher treponemal loads characteristic of secondary and early latent syphilis, in the presence of very high VDRL titers at treatment and at delivery, or if delivery occurs within 30 days treatment.

All pregnant women should be screened for syphilis early in pregnancy at the first prenatal visit and at 36 weeks' gestation or at delivery. An additional screening at 28 weeks is recommended for populations with a high prevalence of syphilis or for individuals at high risk.

TUBERCULOSIS

Tuberculosis is a major world health problem, and the World Health Organization (WHO) estimates one-third of the world's population is infected with *Mycobacterium tuberculosis (M. tuberculosis)*. The prevalence in the United States is 4 to 6 percent. However, many international travelers and immigrants enter the United States each year, so the prevalence may vary.

Transmission of tuberculosis occurs almost exclusively as a result of inhaling infectious particles. These particles are produced when an infected person sneezes and coughs. These particles are 1 to 10 mm in size and remain airborne for prolonged periods of time. Pregnant HCP must be aware of the airborne route of transmission and know that using respiratory protection (e.g., N95 respirator or higher level of respiratory protection) when caring for a patient with suspected or proven tuberculosis will protect her. A pregnant woman is not at increased risk of developing active disease after exposure compared with nonpregnant women.

Currently, the standard screening test for latent tuberculosis infection exposure is the intradermal injection of 0.1 mL of fluid containing five tuberculin units of purified protein derivative (PPD), also known as the tuberculin skin test (TST). Tuberculosis will trigger a delayed hypersensitivity reaction and cause induration. The site is examined 48 to 72 hours after placement. Induration of 5 mm is considered positive in high-risk populations or individuals who have had recent exposure or clinical manifestations highly suggestive of tuberculosis. An induration of 15 mm or more is considered positive in a low-risk population. Induration of 10 mm or more in HCP is considered reactive and requires investigation. An alternative test that would involve serology instead of the intradermal injection is currently under review. The whole-blood interferon gamma release assay is a U.S. Food and Drug Administration (FDA)-approved in vitro cytokine-based assay for cell-mediated immune reactivity to *M. tuberculosis*and might be used instead of TST in tuberculosis screening programs for HCP. This IGRA is an example of a blood assay for *M. tuberculosis*(BAMT). Additional information can be obtained in the chapter that discusses tuberculosis (**95. Tuberculosis and Other Mycobacteria**). Neither pregnancy nor a history of having received bacillus Calmette-Guérin is a contraindication to the use of TST for screening; the frequency of screening is based on the risk assessment for the healthcare institution.

VARICELLA ZOSTER VIRUS

Varicella (chickenpox) and herpes zoster are different manifestations of the same virus. The primary infection is chickenpox when varicella zoster virus (VZV) first infects humans. VZV remains latent for a variable period of time and, when it is reactivated, it presents as shingles or herpes zoster infection.

Because the effects of the varicella virus on the fetus are unknown, pregnant women should not be vaccinated. Nonpregnant women who are vaccinated should avoid becoming pregnant for 1 month after each injection. For persons without evidence of immunity, having a pregnant household member is not a contraindication for vaccination.

Varicella zoster viral particles are transmitted from the respiratory tract via the airborne route, from vesicular lesions by the contact route, or, rarely, by the airborne route with aerosolized vesicular lesions. The infection is highly contagious (90 percent transmission rate to susceptible household contacts) from 1 day before the outbreak of the rash and lasts until the lesions have dried completely. Although this is a disease of children, infection may occur in susceptible adults, and second cases of chickenpox have been documented in the elderly. Apparently 5 cases of varicella per 100,000 pregnancies were expected in the prevaccine era. Incubation period varies from 10 to 21 days for immunocompetent individuals; the average is approximately 14 days after exposure. Fever occurs and is followed by a rash that begins on

the face and scalp. It then becomes randomly distributed to the trunk; the palms and soles are spared. New crops continue to appear for 5 days and are present in varying stages.

Chickenpox pneumonia is the most common complication and is expected to occur in 15 to 50 percent of adults when no antiviral treatment is given. Chickenpox pneumonia in pregnancy is more severe than in the nonpregnant adult, with a maternal mortality rate of 41 to 46 percent compared with 11 percent in the nonpregnant adult. Bacterial superinfection of skin lesions, most frequently with group A streptococcus or *Staphylococcus aureus*, may be associated with serious invasive disease, including toxic shock syndrome. Treatment with acyclovir is recommended for the pregnant woman who develops chickenpox.

Fetal death is the result of severe maternal varicella infection, usually accompanied with pneumonia. It has not been shown that the virus causes fetal death or first trimester wastage.

Varicella embryopathy is rare with fewer than 20 cases reported in the literature. The syndrome may include fetal growth restrictions, aplasia of a single limb or chest wall, cicatrization of the skin, and neurologic and ocular abnormalities. In none of the cases has virus been cultured.

HCP without a reliable history of disease should receive the varicella vaccine before pregnancy. Household contacts of pregnant women may receive the varicella vaccine because transmission of the attenuated vaccine virus has not been associated with adverse fetal effects.

A newly released vaccine is now available for prevention of shingles (herpes zoster). It is indicated for persons aged 60 years or greater. It has a 66 percent efficacy in preventing shingles and post hepatic neuropathy. It is contraindicated in immunosuppressed persons.

In December 2012, the FDA approved VariZIG, a varicella zoster immunoglobulin preparation (Cangene Corporation, Winnipeg, Canada) for use in the United States for PEP of varicella for persons at high risk for severe disease who lack evidence of immunity to varicella* and for whom varicella vaccine is contraindicated. Previously available under an investigational new drug (IND) expanded access protocol, VariZIG, a purified immunoglobulin preparation made from human plasma containing high levels of anti-varicella zoster virus antibodies (immunoglobulin G), is the only varicella zoster immunoglobulin preparation currently available in the United States. VariZIG is now approved for administration as soon as possible following varicella zoster virus exposure, ideally within 96 hours (4 days) for greatest effectiveness. The CDC recommends the use of VariZIG for pregnant women without evidence of immunity.

Zoster (shingles) vaccine is not recommended for use in pregnant women. Women should avoid becoming pregnant for 4 weeks following zoster vaccination.

Conclusions

Pregnant and nonpregnant HCP are exposed to the same possible infectious agents. For some infectious agents, vaccines are available, and prudent HCP will become immunized before conception. It is important that employee health services departments educate all women of childbearing age on how to protect themselves before considering pregnancy and educate all pregnant HCP on how to protect themselves and their fetuses. Immunized, pregnant HCP will then protect herself and pass antibodies to her neonate to protect the neonate for 3 to 6 months.

For some infectious agents, there is no vaccine available, and pregnant HCP must rely on Standard Precautions, including the appropriate use of hand hygiene, masks, gown, glove and eye protection, and respiratory protection, when exposure to potentially infectious blood and body fluids is likely. Restricting pregnant HCP from caring for patients with certain known infections (e.g., CMV) is not recommended.

Future Trends

There are currently a number of vaccines under development that will be of importance to HCP who are pregnant or contemplating pregnancy. These include HSV-2 vaccine, CMV vaccine, RSV vaccine, and group B streptococcus vaccine.

International Perspective

Globalization will continue to require that immunization against vaccine-preventable diseases be emphasized. It is especially important to recognize the variations in immunization practices among all countries. When providing medical care for immigrants and international travelers, it is important to be aware of this potential lack of immunization and, in many cases, presume that the individual is vaccine naïve and proceed with the primary series of indicated vaccines. In addition, increasing international travel can be expected to result in new types of infection that may affect the health and safety of pregnant and nonpregnant HCP. Emphasis on the health and safety of the pregnant woman, as well as the fetus, must include immunization as an effort to reduce illness in the newborn.

* Evidence of immunity to varicella includes (1) documentation of age-appropriate vaccination with varicella vaccine, (2) laboratory evidence of immunity or laboratory confirmation of disease, (3) birth in the United States before 1980 (except for healthcare personnel, pregnant women, and immunocompromised persons), or (4) healthcare provider diagnosis or verification of a history of varicella or herpes zoster. For immunocompromised children aged 12 months to 6 years, two doses of varicella vaccine are considered age-appropriate vaccination.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

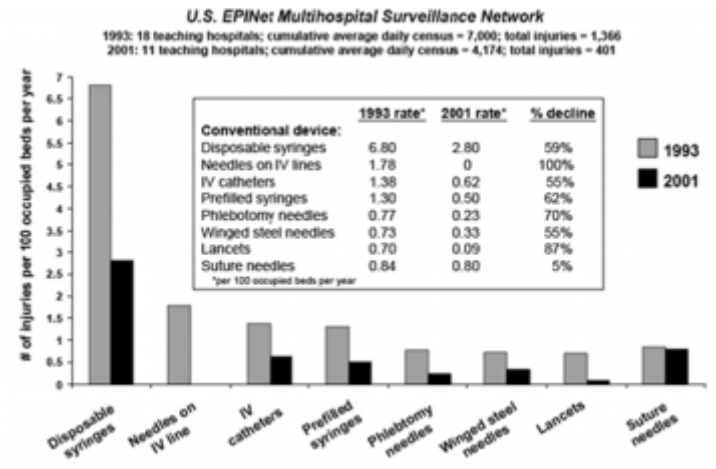
Minimizing Exposure to Blood and Body Fluids

Author(s): Sonia Miller, RN, BSN, MSN, CIC
Chief, Infection Prevention & Control

Fort Belvoir Community Hospital
Fort Belvoir, VA

Published: October 3, 2014

Abstract



Occupational exposure to contaminated medical devices, specifically percutaneous injuries from contaminated sharps, account for the largest number of healthcare personnel exposures to blood and other potentially infectious materials. To minimize this exposure risk, the most solid base for healthcare personnel safety includes evaluation, selection, and implementation of engineering controls; safe work practices; comprehensive safety programs; and annual review of those elements. This chapter will review device-related causes of sharps injuries, available technologies for reducing injuries, and procedure- and device-specific exposure control measures. A brief discussion will be presented on international healthcare personnel safety and public health relating to exposures to blood and other potentially infectious materials.

Key Concepts

- Identify trends in percutaneous injuries from contaminated sharps in healthcare settings
- Present information on available and appropriate engineering controls
- Establish strategies for the evaluation, selection, and implementation of engineering controls (e.g., safety-engineered medical devices)
- Provide interventions and implementation practices for incorporating engineering and work practices into patient care
- Provide suggestions, next steps, and international perspectives on the use of safety-engineered medical devices, safe medication delivery, and safe work practices in healthcare

Background

Percutaneous injuries among healthcare personnel (HCP) continue to pose a significant public health risk for transmission of human immunodeficiency virus (HIV), Hepatitis B virus (HBV), Hepatitis C virus (HCV), and other bloodborne pathogens.[1]This is despite a significant decline in the percutaneous injury rates (Figures 105-1 and 105-2),[2]which is attributed to institutional compliance with the Bloodborne Pathogens Standard published by the Occupational Safety and Health Administration (OSHA) in December 1991.[3]Although needlestick injuries among hospital-based HCP in the United States have decreased to 38[4],325 per year in 2000 from an estimated 800,000 to 1 million exposures per year in 1996,[4]every exposure should be regarded as preventable given the potentially disastrous consequence, as illustrated by the following account:

Conventional device:	1993 rate*	2001 rate*	% decline
Disposable syringes	6.80	2.80	59%
Needles on IV lines	1.78	0	100%
IV catheters	1.38	0.62	55%
Prefilled syringes	1.30	0.50	62%
Phlebotomy needles	0.77	0.23	70%
Winged steel needles	0.73	0.33	55%
Lancets	0.70	0.09	87%
Suture needles	0.84	0.80	5%

*per 100 occupied beds per year

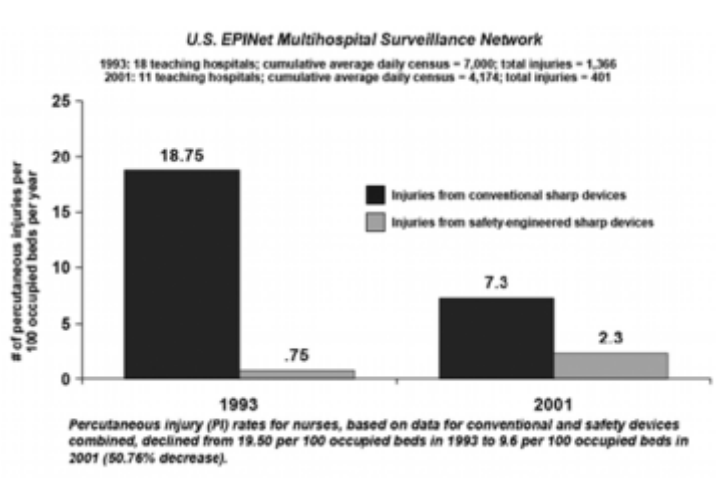
Near the end of a 12-hour shift in the emergency department, I left the triage area to help a colleague having trouble drawing blood from a patient. It was a moment that changed my life. Seconds later, my gloved index finger was bleeding. I had sustained a deep puncture wound from a needle protruding from an overfilled sharps disposal box. That was 1998. By early 1999, I learned that I had contracted HIV and hepatitis C. The incident signaled the beginning of the end of my 26-year career as a front-line nurse and, for some time, transformed me from caregiver to patient.[5]



Although sharps injuries may be decreasing as a result of implementation of safer devices and new non–needle-based technologies,[6,7,8,9]coupled with increased awareness of risk from effective training programs for HCP, it remains difficult to measure the true impact because original surveillance data was acquired through best available sources riddled with misreporting and underreporting of actual exposure incidents. Most data were based on a voluntary reporting system designed by the University of Virginia International Healthcare Worker Safety Center, individual health systems, and state-based reporting systems. Substantial risk for exposure to bloodborne pathogens is burgeoning outside the hospital setting, including nursing homes and residential care facilities, as demonstrated by data from the 1998 to 2000 National Electronic Injury Surveillance System (NEISS), a stratified probability-based sample of U.S. hospital emergency departments.[10]

A comprehensive approach is needed to reduce the risk for exposure to blood and other potentially infectious materials, including the use of Standard Precautions,[11]the implementation of effective disposal systems, worker training and education, and healthcare management safety system buy-in, all of which have contributed to improvements in the safety of the healthcare work environment. Adherence to

Standard Precautions calls for consistent application of infection prevention practices for every patient encounter regardless of a patient's infection status and includes the use of hand hygiene, use of personal protective equipment (e.g., gloves, gown, mask, eye protection, or face shield, depending on the anticipated exposure during direct patient care or contact with potentially contaminated environment), and safe injection practices. Engineering controls target efforts toward using technological strategies to eliminate or minimize exposure to occupational hazards. In the healthcare setting (and with respect to this chapter), this is addressed by the control of occupational exposure to blood and other potentially infectious materials through the use of needleless systems, safer medical devices (such as safety-engineered syringes, intravenous catheters, disposal containers, and adhesive catheter securement devices), and alternative drug delivery systems.

This chapter will focus on only one element of a successful exposure prevention program—the use of engineering controls emphasized by stringent work practice controls.

Basic Principles

Performance-based regulatory text issued by OSHA is broad-sweeping with regard to exposure control, but its intent is focused and clear. OSHA's Bloodborne Pathogens Standard states that employers are required to use engineering and work practice controls to reduce or eliminate occupational exposure to blood and other potentially infectious materials.[12]With the reduction of exposure to blood and other potentially infectious materials, it is inferred that the risk for exposure to bloodborne pathogens will be reduced to the lowest possible level. With evolving and new technology, employers (e.g., healthcare facilities) must select engineering controls that are effective in reducing injuries from contaminated sharps used for patient care, diagnostic and clinical testing, surgery, and drug and vaccine delivery, to name a few. Safety-engineered devices should be the most appropriate for each specific medical or diagnostic procedure based on a facility's exposure determination and procedures or tasks where exposure to blood or other potentially infectious materials is reasonably anticipated. This will vary from facility to facility depending on the medical and preventive services being performed.

The Needlestick Safety and Prevention Act (NSPA) enacted into law on November 6, 2000, helped clarify OSHA's 1991 standard through the addition of specific examples of engineering controls; additional requirements for device evaluation and employee input to be included in the exposure control plan; and the requirement to maintain a sharps injury log.[13]Injuries from contaminated sharps are not limited to the HCP using them, but often involve other workers coming into contact with contaminated devices, e.g., housekeepers, maintenance personnel, waste haulers. Nearly 40 percent of all injuries occurring from contaminated sharps happen to workers who were not the original user of the sharp device.[14]Hence, it is imperative that a healthcare facility perform a comprehensive review and evaluation of safety-engineered devices to ensure their effectiveness from activation of the safety feature during initial use through disposal.[15]

Thousands of U.S. patents have been issued since 1984 for needles and other medical devices that incorporate injury-prevention features.[16] In 2005, the Food and Drug Administration (FDA) updated its premarket notification process for medical devices with sharps injury-prevention features. All major medical device companies in the United States have marketed devices with safety features as alternatives to conventional devices. The available safety products cover a broad spectrum of sharps devices, including the top device categories identified in the 2011 and 2006 U.S. EPINet reports, and 2002 UK EPINet surveillance systems (Table 105-1),[17,18,19] which account for the majority of the reported percutaneous injuries. The basic concepts underlying new safety products include the elimination of unnecessary needles and sharps items (e.g., needleless connections in intravenous [IV] lines) and the incorporation of features that shield hands from needles after use, allowing hands to remain behind needles as they are covered.[20] Sheathing, retracting, and blunting needles are available safety design approaches. A passive safety device that automatically covers the sharp during use may be more effective at reducing needlestick injuries than one that has to be activated.[21]

Table 105-1 Percutaneous Injury Rates for Top 5 Devices: 2011 and 2006 U.S. EPINet Surveillance Network Data Compared to the 2002 UK EPINet Surveillance Data

Device Type Causing Injury	2011 U.S. EPINet	2006 U.S. EPINet	2002 UK EPINet*
Disposable syringe	37.4%	29.3%	25.7%
Suture needle	18.6%	21.9%	8.8%
Winged steel needle	2.5%	5.6%	6.0%
IV catheter (stylet)	3.9%	2.9%	6.3%
Scalpel, disposable	3.0%	4.6%	4.1%
Lancet	0.4%	1.2%	2.9%

*From Be Sharp, Be Safe campaign by the Royal College of Nursing.

This chapter reviews device-related causes of percutaneous injuries and provides a general description of the range of available technology designed to reduce injury risk. Discussion of this technology does not imply endorsement of any specific product. In fact, the availability of such safety technology in the United States may be well in advance of research, particularly randomized trials that would document safety efficacy, user acceptance, and cost effectiveness of specific products. Although reports have been published on the effectiveness and performance of specific safety products, the reports are few compared to the large number of available products, and the findings of these reports are in some cases inconsistent with each other because of different study methods and different circumstances under which the devices were used.[22,23,24,25,26,27,28] Therefore, there is a pressing need for research to evaluate the new technology and alternative means of drug and therapeutic delivery for both HCP and patient safety. Guidelines for conducting product evaluation research and cost-effectiveness analysis of products designed to prevent percutaneous injuries have been described in the literature.[29,30] Further research applying consistent and rigorous methods will ultimately assist healthcare institutions in making optimum product decisions that will afford their employees and patients the greatest safety margin at the highest value.

MINIMIZING EXPOSURE TO BLOOD AND BODY FLUIDS

Exposure Prevention Strategies Related to Blood Drawing

Blood-filled, hollow-bore needles, the devices most frequently associated with bloodborne pathogen transmission, primarily include devices that have been used for vascular access or blood drawing.[1]

Because of the disproportionate rates of pathogen transmission associated with blood-drawing equipment and IV catheters and the wide array of safety products available, the prevention strategies relevant to these procedures will be presented first.

Equipment used in blood-drawing procedures has been associated with phlebotomy injuries. This equipment includes butterfly-type needles, vacuum-tube phlebotomy needles, disposable syringes, and blood gas syringes. Other devices used to draw blood that have caused injuries resulting in bloodborne-pathogen transmission include fingerstick and heelstick lancets, glass vacuum or specimen tubes, and glass capillary tubes.

Protective designs currently exist for every category of device related to blood drawing, including:

- Shielded or self-blunting needles for vacuum-tube phlebotomy sets
- Plastic vacuum/specimen tubes resistant to breakage
- Retracting, sheathing, or blunting butterfly-type needles
- Blunt cannula blood transfer devices
- Blood gas syringes (used for other purposes as well) with a hinged needle shield that can be put in place over the needle without using the hands
- Automatically retracting fingerstick and heelstick lancets
- Unbreakable plastic capillary tubes for hematocrit determination
- Hemoglobin reader (providing a value that translates into a hematocrit value) that does not use capillary tubes or require centrifugation of the sample

There are relatively few publications on the performance of these devices, though anecdotal reports abound and guidelines for evaluating their safety performance have been published.[29,30,31]One study reported a 76 percent reduction in injury rates for a safety vacuum-tube phlebotomy set with a self-blunting needle when compared to a conventional phlebotomy needle and a 25 percent reduction in injury rates with a butterfly-type needle that incorporates a protective sliding shield as compared to a conventional butterfly needle.[27]Another study reported an injury reduction of 82 percent with a vacuum-tube phlebotomy device incorporating a needle-shielding tube holder.[22]

Injecting blood into vacuum tubes using conventional syringes is a hazardous practice and should be prohibited. The needle can miss the stopper and stick the opposing hand, the stopper can "blow off" when injecting blood into the tube, or the needle can suddenly disengage as it is being pulled out of the stopper, rebounding and sticking the worker.[20]In a survey of members of a professional phlebotomy association, 63 percent of respondents indicated that they regularly inject blood through stoppers into tubes.[32]This hazardous practice can be avoided by using a device that draws blood directly from the patient (or from a line) into the vacuum tube or other specimen container. When drawing blood with a syringe is absolutely necessary, transfer of blood into a tube should be done with a blunt cannula blood transfer device.

Eliminating the use of unnecessary blood-drawing needles is also important. Needles should not be used on syringes for the purpose of drawing blood samples from venous or arterial lines. Needleless access equipment (blunt cannula, valve systems) should be used instead. For blood culture procedures, needles should not be changed before the inoculation of culture medium because this practice increases the risk for needlestick and has not been shown to reduce contamination of culture specimens.[33]

Removing contaminated needles from blood collection sets is an extremely hazardous practice. When using a blood tube holder with needle attached, the entire unit should be disposed of immediately after use. Using holders with push-button releases or unwinders should be avoided because the increased manipulation required to remove the contaminated needle increases the risk for an injury. A Safety and Health Information Bulletin published by OSHA in 2003 on the hazards of tube holder reuse and needle removal further clarified the organization's position that removal of a contaminated needle is prohibited by the Bloodborne Pathogens Standard unless the removal is required for a medical procedure.[34]Single-use tube holders with safety-engineered needles attached should be evaluated and implemented to reduce injuries occurring from the unprotected back end of the needle when disassembly is performed. Disassembling devices account for nearly 3.2 percent of all injuries from contaminated sharps reported to 2011 EPINet.

Retracting fingerstick and heelstick lancets minimize the risk for sustaining accidental injuries because the lancet automatically retracts after piercing the patient's skin. Retracting lancets also reduce or eliminate (depending on the design), the possibility of cross-contamination between patients because no reusable components come into contact with the puncture site.

Microbore glass capillary tubes are commonly used for measuring hematocrit. They are extremely fragile and can inflict a large laceration when they break during handling or during centrifugation and are extremely hazardous because they contain blood. All injuries from microbore glass capillary tubes are preventable because unbreakable plastic capillary tubes are currently available. Given the seriousness of the injuries they cause and the widespread availability of safe and inexpensive alternatives, the use of microbore glass capillary tubes should be immediately and completely discontinued. Other methods of measuring hematocrit, such as a hemoglobin reader that does not require centrifugation of blood samples, can also provide safer alternatives.

Summary of Safety Recommendations for Blood-Drawing Procedures

The following recommendations should be observed in blood-drawing procedures:

- Blood-drawing devices with integrated safety features designed to prevent percutaneous injuries should be rapidly implemented, including phlebotomy needle/tube holder assemblies, butterfly-type devices, and syringes used for blood drawing. These devices should be closely monitored for user and patient safety and for reliability of laboratory values.
- All unnecessary needles should be eliminated from use, including needles used for drawing blood from intravenous, arterial, and central lines, and replaced by needleless or blunt cannula devices. In addition, the practice of changing needles for blood-culture phlebotomy should be abandoned to avoid the hazard of manually removing a blood-filled needle from the syringe.
- The practice of injecting blood through a stopper into a vacuum tube using an exposed needle should be discontinued. Methods of drawing blood directly into vacuum tubes or other specimen containers or use of a transfer device should be preferentially employed; alternatively, safety syringes with a cylindrical needle shield locked in place over the needle, which allow a vacuum tube to be inserted

into the shield during blood injection, will reduce needlestick risk and reduce risk of blood splatter from dislodged tube stoppers.

- Automatically retracting fingerstick and heelstick lancets should be used in place of manual lancets or nonretracting spring-loaded lancets.
- The use of microbore glass capillary tubes for measuring hematocrit should be immediately and completely discontinued. Plastic capillary tubes or alternative methods of measuring hematocrit that do not require capillary tubes should be used.
- Glass blood collection tubes should be replaced by breakage-resistant tubes (e.g., plastic, coated glass).
- Blood-drawing personnel should not remove contaminated needles from blood collection tubes to reuse the tube holder. Following a blood draw, the safety feature should be activated and the needle with the attached tube disposed of as one unit immediately after use.
- Blood-drawing personnel should be advised not to manually recap or remove needles from blood-drawing devices, including blood tube holders.
- Blood-drawing personnel should be explicitly advised not to cut the tip off the index finger (or any other part) of procedure gloves because this increases the risk for blood exposure.
- All facilities should provide puncture-resistant disposal containers within arm's reach of blood-drawing personnel for all phlebotomy procedures.

Engineering Controls for IV Catheters

Preventing injuries from IV catheter stylets is just as critical as preventing injuries from blood-drawing devices because the IV catheter stylets are both large bore and blood filled and therefore can result in a higher probability of infection. Several cases of HIV transmission have been attributed to IV catheter stylets.[35,36,37,38]Safety devices are available that provide a protective shield for the stylet before or during its withdrawal from the catheter. A study conducted in three hospitals showed an 83 percent reduction in needlestick rate when a shielded-stylet safety catheter used in the hospitals was compared to a conventional catheter used simultaneously in the same hospitals.[39]Because of the seriousness of IV catheter stylet injuries and because initial results show device efficacy, it is important for institutions to implement safety IV catheters as quickly as possible and to the full extent that is clinically feasible (barring some clinical applications requiring features that a specific device may not have). The devices should also be monitored in each institution for both user and patient safety. In addition to implementing protective IV catheters, procedure gloves should be worn during the insertion of IV catheters, and a puncture-resistant sharps disposal container should be located within arm's reach of HCP or brought to the bedside for all IV catheter placements.

Other Device Categories

Disposable syringes are the most common cause of reported needlesticks in hospitals, as shown in Table 105-1. The level of risk from a syringe needlestick depends on whether the syringe was used for blood drawing or for injection. The possibility of pathogen transmission, including HIV, HBV, and HCV, should not be dismissed, even under low-risk conditions. It also remains important to prevent needlesticks from syringes because in many cases the original purpose of the device, and/or the source patient on which it was used, cannot be identified, and exposed HCP may have to follow the postexposure protocol for an HIV exposure as a precautionary measure.[1]

The elimination of unnecessary needles from the healthcare workplace is a major safety goal. Needles used to connect IV lines or access IV ports are the primary source of unnecessary needles in U.S. hospitals and account for a high proportion of needlesticks in hospitals where they are used. In one U.S. hospital, 25.8 percent of needlesticks from hollow-bore needles were caused by needles connecting to or accessing IV lines, before the introduction of a needleless IV system.[40]The 1992 FDA safety alert advised hospitals against the use of hypodermic needles with IV systems and noted that in addition to the risk for injury to HCP, patients are at risk as well from needles breaking off inside IV ports and from the unintentional disconnection of IV lines when needles pull out of IV ports, both of which can have potentially serious consequences for patients.[41]Since then, approximately 90 percent of IV catheters and IV access devices, some 80 percent of blood collection devices, and 65 percent of needles and syringes used within U.S. hospitals are safety devices.[42]Needleless access to IV lines with the use of stopcocks and Luer locks has been standard practice for decades in European and most other developed countries.[40]

Hypodermic needles accessing IV ports are less likely than blood-drawing needles to transmit a significant infectious inoculum during a needlestick. Nevertheless, bloodborne pathogens can be transmitted by hypodermic needles used for intermittent IV therapy under specific circumstances. One reported HIV case involved an injury from an intermittent IV needle that was connected to a heparin lock close to the patient, in which blood had backed up into the IV line, filling up the needle.[43]The potential for this high-risk combination of circumstances should be taken into consideration when assessing the hazards of conventional IV equipment.

Because of the wide variety of needleless and protected-needle IV systems currently available,[44]and the relative lack of data on performance, few generalizations can be made that apply to all systems. Some studies have documented substantial declines in injuries related to IV equipment after the introduction of needleless systems.[23,25,45]Other authors emphasize the importance of in-service training and enforcement of use of new equipment for successful implementation of new IV systems.[9,26]In light of the need for performance data on many of the new IV products, all IV systems should be continuously monitored for both patient and HCP safety.

Suture needles ranked second as a cause of reported percutaneous injuries in U.S. hospitals, accounting for 18.6 percent of all percutaneous injuries in 2011 U.S. EPINet data.[17]In the surgical setting, suture needles cause more injuries than any other device. Because underreporting is more prevalent among operating room personnel than workers in other areas of the hospital, the true frequency of suture needle injuries is likely to be much higher,[46]with some data showing an increasing trend.[47]Furthermore, surgeons have been shown to sustain higher rates of percutaneous injuries than other HCP.[48]These high injury rates and the frequency of suture needle injuries, however, do not appear to translate into proportionately high rates of bloodborne pathogen transmission. For example, of the 186 documented and possible cases of occupational HIV transmission in the United States reported by the Centers for Disease Control and Prevention (CDC) as of December 1997, six surgeons were listed in comparison to 34 clinical laboratory technicians (most of them phlebotomists).[32,49,50]Among the factors that may account for this discrepancy is that surgeons, in contrast to phlebotomists, are unlikely to be injured by blood-filled hollow-bore needles, the devices most often associated with bloodborne pathogen transmission.

Suture needles have a much smaller potential for transferring a significant quantity of blood during a needlestick, especially after passing through one or two layers of latex or other glove material.[51]

According to U.S. EPINet data from 1995, 86.2 percent of phlebotomists reporting percutaneous injuries were injured by hollow-bore, blood-filled needles. By contrast, only 3.1 percent of physicians reporting injuries in the operating room were injured by blood-filled, hollow-bore needles. It is still important to prevent suture needle injuries, however, to reduce the need for postexposure follow-up and patient testing, minimize interruptions of surgical procedures, and also minimize the potential for patient exposure to blood of the injured surgical personnel. The risk for surgeon-to-patient HIV transmission is small, but it is nevertheless a realistic concern. The French Ministry of Health disclosed the first probable case of surgeon-to-patient HIV transmission in 1997.[52]Suture needles are unique in that the majority of suture needle injuries occur during, rather than after, use of the needles. In 2011 U.S. EPINet data, 18.6 percent of suture needle injuries occurred during suturing and 3.2 percent occurred during passing or disassembly. Therefore, prevention measures that can reduce injuries during, as well as after, suturing will have a much greater potential for injury reduction than measures that target disassembly or disposal only.

Blunt suture needles are available that are not sharp enough, under normal conditions, to cause percutaneous injuries to HCP but are sharp enough to penetrate internal tissues such as muscle and fascia.[53]The potential for injury prevention depends on the proportion of suturing that can be performed with blunt needles. One study reported an 83 percent decline in suture needle injury rates following the introduction of blunt suture needles during gynecological surgery,[54]with blunt suture needles causing no injuries. Another prevention approach is to reduce the use of suture needles and other sharp surgical instruments to a minimum. For example, using stapling devices, adhesive strips, or tissue adhesives for wound closure reduces the use of sharp suture needles.

Injuries from disposable scalpel blades rank fourth as a cause of percutaneous injury, contributing 3 percent of all injuries in 2011 U.S. EPINet (see Table 105-1), with reusable scalpels contributing to an additional 4 percent of the injuries.[17]Scalpel blade injuries most frequently occur in the operating room, with the highest proportion occurring during use, followed by injuries during passing and disassembly. Scalpel blades are more likely than needles to cause deep or otherwise severe injuries resulting in moderate or profuse bleeding. Hence, injuries caused by scalpel blades are associated with a greater likelihood of significant blood contact between patients and surgical personnel. One case of HIV transmission in a surgeon following a scalpel injury has been documented in the Italian SIROH study.[55]

Another case of HIV transmission following a scalpel injury that occurred during an autopsy has been documented in a U.S. pathologist.[56]

A variety of prevention alternatives target the different mechanisms of scalpel blade injuries. Options for preventing injuries that occur during cutting include using alternative cutting methods when appropriate, such as blunt electrocautery devices and laser devices, substituting endoscopic surgery for open surgery when possible, using round-tipped scalpel blades instead of sharp-tipped blades, using retractable, disposable scalpels, using alternative materials (e.g., silicone) blades, and avoiding manual tissue retraction by using mechanical retraction devices.

Scalpels with safety features include retracting-blade and shielded-blade scalpels and have the maximum potential to prevent injuries that occur during passing, after use, and during and after disposal. Devices that allow the nonmanual release of scalpel blades from reusable handles provide a method for reducing injury risk during disassembly of scalpels. Such devices include scalpel handles that

release scalpel blades and accessory devices that mechanically remove blades. The use of disposable scalpels, which does not require blade removal, also has the potential to prevent disassembly-related injuries.

Possible prevention strategies for injuries that occur during passing of scalpels include a policy of hands-free passing of instruments, which is intended to minimize collisions between hands and sharp instruments by designating a neutral zone where instruments can be placed and picked up. Although there are no randomized, controlled trials showing efficacy of the hands-free technique in reducing injury risk, despite its effectiveness being demonstrated in a prospective study of 3,765 surgical procedures in a U.S. inner city hospital,[57]its use remains inconsistent.[58]

Although no gloves provide total protection from needlesticks, there are gloves that can be worn under latex, vinyl, or nitrile gloves that resist laceration. These gloves have been made in a variety of materials, such as steel mesh, Kevlar, leather, and a knitted cut-resistant yarn.[59]Laceration-resistant gloves are particularly applicable to the pathology and autopsy settings, where scalpel blades are the most frequent cause of injury and where touch sensitivity is not as critical as in surgery. The gloves can be worn on the nondominant hand, which is where the majority of scalpel injuries occur.[60]

In addition to the specific recommendations for preventing suture needle and scalpel blade injuries, especially in the surgical setting, an evaluation of all surgical instruments should be conducted to eliminate equipment that is unnecessarily sharp. For instance, towel clips have been identified as a cause of injury in the operating room, yet blunt towel clips are available that cannot cause percutaneous injuries and are adequate for securing surgical towels and drapes. Surgical scissors, surgical wire, electrocautery needles, and pick-ups are further examples of devices that do not always need to be sharp.

Conclusions

Implementation of safety-engineered medical devices is beginning to take shape as a great public and occupational health success story. Through the use of safety disposable syringes, safety blood-collection sets, needleless IV systems, and blunt suture needles, injuries from contaminated sharps have been reduced. Public policy requires the use of engineering and work practice controls, and healthcare systems have recognized not only the need to comply with federal law, but also the need to implement systems that reduce injuries to HCP to best add value to overall safety programs, reduce lost work days, reduce emotional turmoil after an injury, reduce costs associated with postexposure follow-up and prophylaxis, and reduce costs associated with workers' compensation and insurance premiums. Available technologies give healthcare facilities a broad range of options for selection based on clinical needs, worker and patient safety, accuracy of medication delivery, and better patient care.

It is clear that more and better injury data are needed, especially in nonacute care sites. For now, the use of engineering controls has reduced injury rates in nearly all medical specialties in hospitals and other acute care facilities, but the continuation of safety conversion in nursing homes and nontraditional healthcare settings needs to be emphasized further. It is also clear that injuries are still occurring when safety-engineered devices are used because of poor selection, poor work practices, device failure, patient movement, or other reasons; alternative technologies for medication delivery would further reduce sharps injury numbers. For example, newer technologies for drug delivery include the use of medication skin patches, forced air injection systems, and alternative methods for medication absorption, such as oral, nasal, or epidermal.

Future Trends

Reductions of injuries from contaminated sharps will continue over time because of the implementation of engineering controls. New non–needle-based technologies will emerge that will further reduce percutaneous injuries in healthcare settings. More surveillance data should be collected from healthcare facilities to assess the success of engineering controls from use of more effective technologies. A root-cause analysis should be conducted to identify departments and specialties with high rates of injuries and to determine reasons these safety-engineered medical devices have not been implemented. As acute care facilities implement safety devices, it will be important to monitor alternative sites or smaller healthcare-providing businesses, such as medical offices, surgical centers, dental offices, and nursing homes to better propagate conversion to safety. Several industries outside typical healthcare that have potential for blatant exposures to blood and other potentially infectious materials should be included for future research, such as funeral homes and mortuaries, piercing and tattoo parlors, and commercial fishing.

Societal issues will emerge as the public becomes more aware of bloodborne pathogens and the importance of preventive measures to reduce the incidence of transmission. Although occupational risk of HBV transmission in our younger generations entering the healthcare workforce systems will decrease in the coming decades as a result of universal childhood immunization, risk for injury will increase for other community workers, including waste haulers, from widespread use of self-injector therapies such as insulin and hormones generating contaminated devices that enter the waste stream. Therefore, it will be important to look toward transitioning all sharps to safety devices to reduce injury rates in and out of the healthcare systems.

International Perspective

Modeled after the U.S. rules and regulations for the protection of HCP, other countries have begun the process of influencing national policies. Several countries in Europe have introduced safety policies and regulations for HCP safety. Other countries have begun the formation of safety committees and coalitions with visions for HCP safety policy. It is interesting to monitor progress internationally and to see how laws and policies put in place are effectively reducing bloodborne pathogen transmission in healthcare. A global perspective for HCP safety will benefit each country and each system to better compare and contrast measures of success and failure and to implement the most effective programs.

Reuse of contaminated devices from citizen to citizen in Third World countries perpetuates a high rate of disease transmission for HIV, HBV, and HCV. Undoubtedly, mass vaccination programs will serve as valuable public health preventive measures and the benefit of effective engineering controls will remain primary. However, the use of autodisabling syringes will further reduce disease transmission because each syringe is rendered unusable after each injection. Proper sharps disposal will also reduce injuries internationally for these workers and citizens downstream.

Abstract

Sterile processing is the area most often responsible for reprocessing and sterilizing instrumentation and other reusable medical devices. The process involves handling, collecting, transporting, sorting, disassembling, cleaning, disinfecting, inspecting, packaging, sterilizing, storing, and distributing reprocessed items. The goal is to provide safe, functional, and sterile instruments and medical devices to reduce the transmission of pathogenic organisms from patient to patient and to reduce the risk for surgical site infection. This chapter offers the infection preventionist an introduction to the numerous processes that take place in sterile processing and provides access to resources, published recommended practices, standards and guidelines, and industry standards. The chapter also offers suggested readings to expand the infection preventionist's knowledge of current concepts and practices in sterile processing.

Background

The history of sterile processing (SP) has its beginnings associated with the history of sterilization. Sterilization is less than 200 years old. With Louis Pasteur's germ theory, recognized in the mid-1800s, the foundation for sterilization of medical devices was established. This theory proposed that germs were related to illness, which laid the foundation for improving healthcare practices in surgery and clinical units and provided the evidence base for disinfection and sterilization.[1,2]Charles Chamberland, a

student of Louis Pasteur, developed the first sterilizer in the mid-nineteenth century. Its design was similar to a pressure cooker, and it allowed for the destruction of microorganisms. The sterilizers were initially placed in the operating rooms, with surgical nurses responsible for the sterilization process.[1,3]

Because of the increase in surgical cases and the increased demand for reprocessing of surgical instruments and equipment, the tasks of handling, collecting, transporting, sorting, disassembling, cleaning, disinfecting, inspecting, packaging, sterilizing, storing, and distributing medical devices were transferred to a dedicated department that was, at the time, referred to as "central services"—but now is more commonly called "sterile processing." In 1924, Misericordia Hospital, now Mercy Catholic Medical Center in Philadelphia, became the first hospital to establish a physically separate and designated area or department for reprocessing instruments and medical devices away from the operating rooms.[1]In the late 1950s and early 1960s, ethylene oxide (EO) sterilizers were developed to address the reprocessing of heat-sensitive devices.

In recent years, new advances and methods of sterilization and a renewed focus on performance improvement have contributed to the ability of SP to improve efficiency, reduce turnaround, and ensure quality and patient safety.

Basic Principles

The SP area is given the responsibility and accountability for reprocessing contaminated instruments and medical devices, especially surgical instruments and equipment. Work activities include handling, collecting, transporting, sorting, disassembling, cleaning, inspecting, disinfecting, packaging, sterilizing, storing, and distributing reprocessed items. During these activities, it is important for the processing staff to be familiar with the principles of cleaning, disinfection, and sterilization, as well as the equipment manufacturers' written instructions for use (IFU) for reprocessing equipment such as mechanical cleaning equipment and sterilizers, and the IFU for chemical solutions, cleaning tools, disinfectants, packaging, cleaning, and sterilization monitors. These instructions provide the information necessary to safely use, monitor the efficacy, and conduct preventive maintenance to ensure quality and process reliability. The chemical solution manufacturers' recommendations provide guidance on the selection, use, mixing, and monitoring of the effectiveness of chemical agents and how to select the type of water (tap, deionized, or distilled) required for product use. The IFU must be followed for the expected outcome of safe, functional, and sterile items that prevent transmission of pathogens and surgical site infections (SSIs) (**31. Cleaning, Disinfection, and Sterilization**and **32. Reprocessing Single-Use Devices**offer additional information.)

Many facilities allow for the cleaning, decontaminating or disinfecting, and reprocessing of reusable items to take place outside SP areas (in the surgical areas or patient care areas). The infection preventionist (IP) needs to be aware of such practices to make certain that all items are reprocessed according to the same standards in all locations within the healthcare system.

The appropriate use of personal protective equipment (PPE) during high-risk cleaning and disinfecting processes reduces the risk for blood and body fluid exposure for processing personnel. Written policies and procedures promote consistent practice among healthcare personnel.

Reprocessing medical devices requires a collaborative association between SP staff and the clinical staff who use the devices, especially in operating rooms. This team must work together to provide safe, efficient, cost-efficient, and high-quality reprocessing.

Consistent implementation of up-to-date published recommended practices and standards of care and up-to-date IFU will facilitate the achievement of positive patient outcomes and quality services.

Orientation and continued educational training on expected practice and regulations are essential for SP staff. Regulatory agencies include federal, state, and local laws, the Occupational Safety and Health Administration (OSHA), the Environmental Protection Agency (EPA), and the Food and Drug Administration (FDA). The Centers for Disease Control and Prevention (CDC) publishes the Healthcare Infection Control Practices Advisory Committee (HICPAC) guidelines and the Association for the Advancement of Medical Instrumentation (AAMI), and the Association of periOperative Registered Nurses (AORN) publishes healthcare recommended practices and standards. In addition, The Joint Commission (TJC) uses these regulations, recommendations, and guidelines, specifically the most up-to-date ANSI/AAMI ST79 *Comprehensive guide to steam sterilization and sterility assurance in healthcare facilities*, as the standards of practice to which healthcare facilities must adhere for accreditation. Lastly, the Facilities Guideline Institute publishes widely accepted guidelines for designing SP areas.

To improve the education, training, and competency of those responsible for processes in SP, states are beginning to establish certification for SP healthcare personnel. In 2004, New Jersey became the first state in the nation to mandate certification for SP professionals and, in 2013, New York became the second state. The Certification Board for Sterile Processing and Distribution (CBSPD, **www.sterileprocessing.org**) and the International Association for Healthcare Central Service and Materiel Management (IAHCSMM, **www.iahcsmm.org**) offer certification. Several other states are moving in the same direction.

This chapter offers an introduction to the processes and activities that take place in SP and highlights the measures used to ensure safety and quality. The IP should be familiar with these processes when conducting infection control rounds in SP as recommended by HICPAC and should routinely include results of monitoring activities in the infection prevention and control program reports. The reader will find references and suggested readings containing more detailed information.

Table 106-1 identifies general goals for infection prevention for SP.

The following definitions may be helpful[4,5,6,7,8,9,10]:

*Aeration:*A processing step using warm circulating air to enhance the removal of a chemical sterilization agent residue from processed items and wrapping material. Used with EO sterilization.

Biological indicator (BI): A device used to monitor sterilization processes. The device contains a viable population of highly resistant bacterial spores that are resistant to the type or method of sterilization being monitored.

Chemical indicator (CI): A device used to monitor the presence of one or more predefined process parameters required for a satisfactory sterilization process. The six classes of CIs are defined in ANSI/AAMI ST79[4]and in Table 106-2.

Chemical integrator: A Class 5 integrating indicator designed to react to all critical variables of the sterilization process and used as an internal CI, inside the BI process challenge device (PCD) to monitor implant loads, and in a CI PCD to monitor nonimplant loads.

Decontamination: The use of physical or chemical methods to remove, inactivate, or destroy bloodborne pathogens, rendering them no longer able to transmit infectious particles and rendering the decontaminated item safe for handling.

Disinfection: The destruction of pathogenic (disease-causing) microorganisms, usually by physical or chemical means.

Ethylene oxide (EO): Chemical (gas) that is used to sterilize heat- or moisture-sensitive items; also used as a fumigant.

Event-related sterility: Concept that items are considered sterile unless the integrity of the packaging is compromised (i.e., torn, soiled, wet, or showing evidence of tampering). Shelf life is indefinite.

Hydrogen peroxide (H_2O_2) gas with or without plasma sterilization: A popular low-temperature sterilization method used to process heat- or moisture-sensitive items because of its short cycle and faster turnaround time but with packaging and lumen limitations.

Immediate-use steam sterilization (IUSS)(formerly called flash sterilization): Process designed for the cleaning, steam sterilization, and delivery of patient care items for immediate use.

Parametric release: Declaration by medical device manufacturers that a product is sterile on the basis of physical or chemical process data after validating the cycle using BIs.

Pasteurizer: Equipment that uses hot water for a definite period to destroy pathogenic bacteria; often used for respiratory therapy and anesthesia equipment.

Peracetic acid: Liquid oxidizing agent used in automated endoscope reprocessors. Items processed with this agent need to be used immediately because they are wet and cannot be packaged and stored for later use.

Physical monitors (previously called mechanical indicators): A visible monitor (time, temperature, and pressure recorders, digital printouts, and gauges) that enables the operator to determine if sterilizing parameters were met.

Process indicators: Class 1 CIs used as an external CI on the outside of packages or containers to demonstrate that the unit has been exposed to the sterilization process and to distinguish between processed and unprocessed units.

Process challenge device (PCD): Item designed to create a challenge to the sterilization process and used for routine and qualification testing of sterilizers. Previously referred to as a test pack.

Stated value (SV): Part of the CI labeling that provides a value or values of a critical variable at which the indicator is designed to reach its end point as defined by the manufacturer. For example, a Class 5 integrating indicator with a stated value of 2.1 minutes at 135°C should reach its end point when tested at 135°C for 2.1 minutes in a resistometer.

Sterile: State of being free from all living microorganisms.

Sterility assurance level (SAL): Probability of a single viable microorganism occurring on an item after sterilization. SAL is normally expressed as 10^{-6}, which means there is less than or equal to one chance in a million that a single viable microorganism is present on a sterilized item.

Sterilization: A validated process by which all viable forms of microorganisms (including spores) are destroyed.

Sterilizer: Equipment used to sterilize medical devices, equipment, and supplies by direct exposure to a selected sterilization agent.

Sterilizer, EO: Sterilizer using EO gas under defined gas concentrations and selected temperature, time, and relative humidity to sterilize heat- and moisture-sensitive medical devices.

Sterilizer, steam, gravity-displacement: A sterilizer in which incoming steam displaces residual air through a drain (usually in or near bottom of chamber). There are selected time and temperature parameters needed for correct operation.

Sterilizer, steam, dynamic-air-removal: Types of sterilization cycles in which air is removed from the chamber and the load by means of a series of pressure and vacuum excursions (prevacuum cycle) or by means of a series of steam flushes and pressure pulses above atmospheric pressure (steam-flush pressure-pulse [SFPP] cycle).

Sterilizer, steam: A sterilizer with saturated (greater than 97 percent) steam as a sterilant and pre-established time, temperature, and pressure or vacuum settings.

User verification: Documented procedures performed by SP in a healthcare facility to determine that the specifications for sterilization as defined by the medical device manufacturer have been met.

Validation: Procedures documented by medical device manufacturers to establish that a process will consistently yield products that comply with predetermined specifications when instructions for processing are followed by SP in a healthcare facility.

Table 106-1 lists infection prevention goals for sterile processing that are discussed further. This tool can be used for the SP infection control and prevention rounds or audit.

Table 106-1 Infection Prevention Goals for Sterile Processing

Point of Use/Transport *At the earliest stage possible, following a procedure, prevent organic matter from drying on instruments and microorganisms from growing on devices.* • Keep instrumentation moist so that bioburden is not dried onto the device. • Clean devices before biofilm can form. • Contain contaminated devices to prevent accidental exposure to staff and patients.
Physical Environment of the Sterile Processing Area *Prevent environmental conditions that encourage microbial growth and cross contamination.* • Ensure that the airflow moves from areas of low contamination to areas of higher potential contamination. • Ensure the proper air exchange frequency to remove possible airborne contaminants. • Control humidity and temperature levels. • Prevent the formation of substances that protect microorganisms from further processing steps (biofilm). • Ensure that the environment provides appropriate lighting for thorough evaluation of instrumentation for debris. • Ensure staff safety and reduce microbial transport by personnel. • Ensure that hand hygiene products are available and are used.

Decontamination

Protect workers from contamination with possible infectious materials.

• Ensure that air pressure in the work area is negative (pulls air into the work area) with 10 air exchanges/hour and that all air is exhausted to the outside atmosphere.

• Ensure that gloves, masks, eyewear, and gowns appropriately protect staff from contact with contaminated fluids.

• Ensure that PPE prevents contaminated materials from entering the eyes or mouth.

• Reduce the bioburden and microbes to a level safe for use or further reprocessing.

• Ensure that the instrument manufacturer's written cleaning IFU are followed.

• Ensure that the mechanical cleaning of equipment, including use of cleaning solutions, follow the manufacturer's written IFU.

• Ensure that the cleaning chemicals are appropriate, diluted correctly, and not expired.

• Ensure for manual cleaning that the temperature of the cleaning solution and soaking time is monitored and documented.

• Ensure that tools and equipment used to remove bioburden are in good working order and effective.

• Ensure that the correct size and type of brushes are used for lumens and, if disposable, are discarded after each use and, if reusable, are decontaminated daily.

• Ensure that all disinfection chemicals are appropriate, within effective concentrations by monitoring, and not expired.

• Ensure that manual disinfection processes are physically monitored with a thermometer and timer and that the results are documented.

• Ensure that the decontamination process used for each device is appropriate for that device.

• Ensure that devices are correctly loaded and lumens attached to the correct lumen irrigators of the mechanical cleaning equipment.

• Ensure that the physical monitors of the mechanical cleaning equipment are read after each cycle and documented.

• Ensure that the decontamination process renders the device safe for patient use (if appropriate) or safe for handling for additional processing (enzymatic cleaners alone do not render items safe).

• Ensure that the effectiveness of the cleaning process is being verified by a commercially available monitor.

Preparation and Packaging

Ensure that pack preparation promotes adequate sterilant penetration so that sterilant reaches all surfaces holding microorganisms.

• Ensure that the air in the work area is under positive pressure, there are 10 downward-draft air exchanges per hour, and that the temperature is 20°C to 23°C (68°F to 73°F) and at a relative humidity ranging from 30 to 60 percent.

• Ensure that packaging materials are held at the temperature and humidity listed above for a minimum of 2 hours before use.

• Ensure that instruments are free of debris and in good working order.

• Ensure that the instrument and packaging manufacturer's IFU are followed and that the packaging is not changed unless validated by the instrument manufacturer.

• Ensure that the packaging material is appropriate for the selected sterilization process.

• Ensure that the packaging configuration does not allow microbes to enter through holes, gaps, or tears.

• Disassemble or position instruments for maximum penetration of sterilant.

• Ensure that any packaged accessories are appropriate for use inside instrument trays.

• Ensure that double-peel pouching is done correctly.

• Ensure that each package has a lot control identifier.

Sterilization

Ensure correct loading, sterilization process, cycle selection, and unloading.

• Ensure that the air in the work area is under positive pressure, there are 10 air exchanges per hour, and the temperature is 20°C to 23°C (68°F to 73°F) and at a relative humidity ranging from 30 to 60 percent.

• Ensure that the sterilizer manufacturer's written IFU is followed for operation and that routine and planned maintenance occurs on schedule.

• Ensure that items are loaded correctly according to the sterilizer and packaging manufacturer's written IFU.

• Ensure that the correct sterilization process and cycle parameters are used as directed by the instrument and packaging manufacturer's written IFU.

• Ensure that items are properly cooled before unloading to sterile storage.

• Capture processing errors that prevent sterilization.

Quality Control

Monitor to detect equipment or operator errors or malfunctions that prevent sterilization.

• Ensure that all the chemical and BI manufacturers' written IFU are followed.

• Ensure that the Bowie-Dick test is performed in each dynamic-air-removal steam sterilizer each day in all locations within the healthcare organization.

• Ensure that every package to be sterilized contains CIs on the outside unless the internal CI is visible and on the inside (internal).

• Ensure that the correct BI process challenge device is being used to monitor all the cycles routinely used, that BI process challenge device IFU are being followed, and that BI frequency is correct.

• Ensure that the BI is incubated at the correct temperature, a positive control from the same lot as the test vial is incubated each day a test vial is incubated, that the correct readout time is used, and that the test and control results are documented.

• Ensure that the correct sterilization cycle was used by reading the physical monitor.

• Read all sterility assurance monitoring devices (physical monitors, external chemical and BIs) before release of the load.

• Evaluate each load before release (e.g., visible tears in wrap or moisture).

• Document and report any incidents in which implants were released for use before the result of the BI.

• Ensure that each internal CI is read before the package is placed on the sterile field.

Recordkeeping

Document the result of the sterilization process.

• Ensure that all sterilization process, sterilizer maintenance, and repair records are documented and that they are maintained in a legible, orderly manner and can be easily retrieved when necessary.

• Ensure that records maintain complete traceability from sterilization through patient use.

• Ensure that implant sterilization and monitoring is traceable to the patient.

Storage

Prevent microbial contamination of sterilized items.

- Ensure that sterilized items are not exposed to extreme temperature differences that result in condensation and contamination.
- Ensure that all storage or transport units do not damage the packaging.
- Ensure that maintenance covers are used when warranted.
- Ensure that the external CI and package integrity are inspected before the item is dispensed.

STERILE PROCESSING

Point of Use

Reprocessing contaminated equipment or instruments for sterilization begins at point of use. The end user is responsible for removing gross soil and debris and for rinsing items at the site of use. Instruments with lumens should be flushed with water (not saline, as salt is corrosive to most instruments). Every attempt should be made to keep instrument or equipment surfaces moist until they can be cleaned to facilitate the removal of soil. Applying enzymatic foam or gel cleaner, using wet towels (water, not saline) placed within the set of used instruments, or presoaking used items in water or cleaning solution are all potential options.[4]

Transportation

Contaminated items should be placed in puncture-resistant leak-proof sealable containers and visibly labeled as biohazardous.[4]The selection of the container (e.g., bins with lids, covered or enclosed carts/containers/totes, impermeable bags, or combinations of each) will depend on the size, presence of sharps (segregated in container), configuration, and volume/numbers of medical devices or instruments being transported. Transporting used instruments submerged in liquids presents additional risk for blood

and body fluid exposures, the promotion of biofilm formation, and the possibility of employee injury because of the weight of the container. The liquids should be discarded while wearing PPE.[4] If off-site transportation is required, follow Department of Transportation, state regulations,[4] and OSHA requirements.

Physical Environment

Adequate space in SP is critical to provide for worker safety, good workflow, and efficient and effective work practices to ensure patient safety. The size of the department must be appropriate for the volume of work being performed, the processes being conducted, the types of services provided, and the amount of equipment required to perform the required tasks. Space needs can be affected by the storage and delivery systems employed by the hospital (i.e., case carts, supply carts, special procedure carts, and storage of durable medical supplies [intravenous pumps, portable suction, etc.]). Fans should never be used in the processing area.[4]

Other considerations that are important in SP are the ventilation, temperature, and humidity in the department. These environmental conditions are noted in Table 106-2.

DECONTAMINATION AREA

Design

The design should include a physical barrier between the decontamination area and the other work areas.[4,5] The floors and walls should consist of nonparticulate/nonfibrous shedding material that can withstand wet vacuuming and washing.[4] The ceiling should have a flush surface with enclosed fixtures and be made from a nonparticulate/nonfibrous material. The work surfaces should be covered with a nonporous material that can withstand frequent cleaning with germicides. The ventilation of the area should have negative air pressure (pulls air into the work area) with 10 air exchanges/hour and all air exhausted to the outside atmosphere.[4] Figure 106-2 summarizes the environmental conditions required for all work areas in SP. Hand hygiene facilities (sinks and waterless alcohol-based hand rubs) should be easily accessible to staff. There should be eyewash stations as identified by OSHA regulation, and safety data sheets (SDSs) for each chemical used within 10 seconds of travel time.[4] Figure 106-1 shows a possible area design for the SP department.

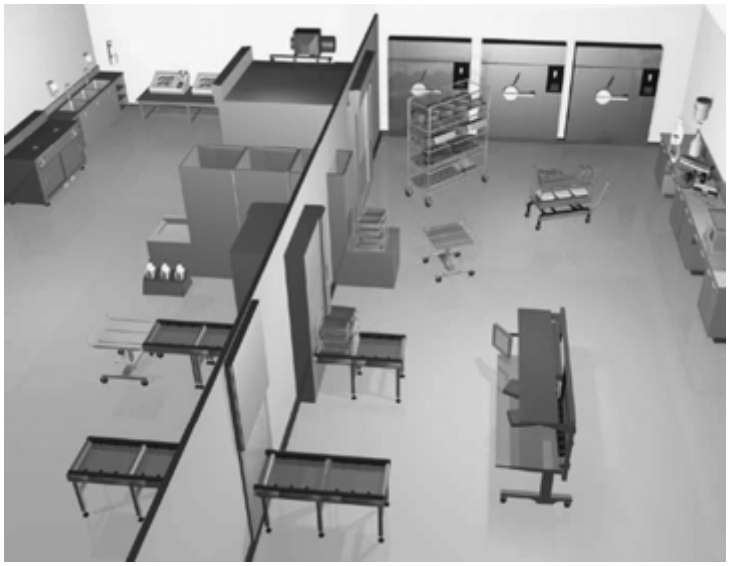

Figure 106-1.

Possible SP area design (courtesy of STERIS Corporation).

Personal Protective Equipment and Other Safety Measures

Handling of soiled instruments and equipment increases the risk for bloodborne pathogen exposure for the SP worker in addition to other disease-producing organisms. Proper use of PPE is critical to ensure a safe work environment and to meet regulatory requirements. Eye protection, in the forms of safety goggles or full-length face shields, should be worn at all times when cleaning soiled equipment.[4,6,7] All hair should be covered with a surgical cap, and a fluid-resistant face mask should cover the nose and the mouth at all times.[4,6,7] A liquid-resistant covering with sleeves (i.e., backless gown, jumpsuit, or surgical gown) should be worn and should cover the arms and clothing. Gloves should be worn to protect users from contact with blood and body fluids, protect from exposure to chemical cleaning

solutions, and offer some protection against sharp objects. General purpose utility gloves that are heavy duty and waterproof should be worn, because they provide more protection than traditional medical examination gloves.[4'6'7]

The gloves should be cuffed and long enough to completely cover the exposed hand, arms, and part of the gown. If reusable, heavy duty gloves are used, the manufacturer's recommendations for cleaning, disinfecting, and duration of use should be followed. Liquid-resistant shoe covers should be worn to protect shoes from blood and body fluid exposures that may occur during the decontamination process.[4]

SP staff should be trained to manage small and large body fluid spills. Figure 106-2 shows an SP employee wearing PPE for use when working in the decontamination area.

Environmental measures, including engineering controls, should include the use of mechanical devices (e.g., hemostats) to retrieve sharps in containers. No consumption of food or drink and no application of lip balm or contact lenses should be allowed in the work area. Sinks and other hand hygiene facilities, as well as an eyewash station for emergencies, should be readily accessible.[4]

Figure 106-2.

Personal protective equipment in decontamination area of sterile | View Image

Disinfecting Work Areas

Routine cleaning of the work environment is essential. Work tables, countertops, and other high-touch horizontal surfaces and floors must be cleaned and disinfected at least daily and as needed.[4]Case carts, storage containers, and transportation carts should be decontaminated after each use.[4]Walls, air-intake and -return ducts, storage shelves, and storage areas should be cleaned and disinfected on a regularly scheduled basis and more often if needed.[4]

Cleaning Used Items

The cleaning process is the most critical step in the sterilization process and should follow the written manufacturer's IFU to ensure that the item is effectively cleaned. Blood, body fluids, and other organic and inorganic soil remaining on medical devices interfere with the sterilization process and, if

they are not removed, the item(s) cannot be considered sterilized. Instruments with removable parts should be disassembled and cleaned before they are sterilized.

The effectiveness of the cleaning process depends on the quality of the water; the quality, concentration, and type of detergent or enzymatic cleaner; an acceptable washing method (manual, mechanical, or both may be required); proper rinsing and drying; correct preparation of items to be processed by mechanical cleaning equipment; the time and temperature parameters and load capacity of the equipment; and operator performance.[4]

The cleaning process includes selecting the correct cleaning product and using it properly. Manufacturers of the various cleaning agents and instruments can recommend the appropriate cleaning solution. Detergent solutions or the combination of detergent and enzymatic solutions are used to clean medical devices. Detergents work by lowering the surface tension, breaking down fats, oils and grease, and soil into smaller particles and suspending them in solution. Enzymatic solutions work by breaking down proteins, fats, carbohydrates, etc. and may be used to soak instruments with crevices or dried-on proteins or fats. Enough rinsing with water to remove chemical residue from the items should follow manual or mechanical cleaning. Refer to the device manufacturer's written IFU to determine if further decontamination using a microbicidal process is needed.[4]The pH of the chemicals is an important consideration, as certain pH levels may be harmful to the instruments being reprocessed.

Manual Cleaning Method

The manual cleaning method is often recommended for delicate or complex medical devices such as ophthalmology or other microsurgical instruments, lensed instruments, and air-powered drills that cannot be processed through automated or mechanical cleaning equipment or cannot be submerged. Instruments that are difficult to clean can also be disinfected manually if required by the instrument manufacturer. Both outer and inner surfaces must be cleaned, so it is critical at this point to disassemble instruments and equipment before cleaning. When cleaning devices with a sprayer, a brush, or other friction-causing process, immersion under water is used to minimize blood and body fluid aerosolization, decreasing the staff's risk for exposure.[4,5]Brushes of the appropriate type, size (diameter and length), and bristle type and material should be used, and the instrument manufacturer should provide this information in writing.[4]Brushes can be single-use disposable or reusable. If reusable brushes are used, they should be decontaminated at least daily.[4]Single-use brushes should be disposed after each use.

Lumens and channels need to be irrigated or cleaned by suction. The irrigation method should include immersing the item during the procedure. The suction method flushes the cleaning solution through the instrument and returns it to a canister.[4,5]The selection of the proper cleaning product for manual cleaning depends on the type of debris or soil left on items, the length of time between use and cleaning, compatibility with the item being cleaned, and the point at which the product makes items safe for handling.

Follow the manufacturer's IFU for manual cleaning. The temperature of the soaking solution should be monitored and documented to ensure that the temperature of the cleaning solution meets the requirements of the cleaning solution's written IFU.[4]A wireless temperature monitor with a probe that is placed into the solution to transmit data wirelessly via a wifi network to a PC is available. The time the instruments are soaked should also be recorded. The next step is thoroughly rinsing with tap water to

remove residue, followed by a final rinse with treated water such as deionized, distilled, or reverse osmosis water. The treated water is necessary to prevent staining of instruments, which prolongs their life and prevents adverse reactions in the patient.[4]

A water-soluble instrument lubricant in a lubricant bath or rinse (e.g., milk bath) may be used on instruments to maintain the function of hinges. The instruments should then be dried with air or a lint-free cloth before packaging.[4]

Endoscopes, powered equipment, or complex items require special attention but still require precleaning before processing. The staff must follow the manufacturer's written IFU for cleaning. The design of some medical devices may not permit steam sterilization and may be candidates for EO or other low-temperature gas sterilization processes, or they can be processed in an automated endoscope reprocessor. Again, the manufacturer's recommendations will stipulate the manner and method for reprocessing equipment.

Mechanical Cleaning Methods

Multiple devices and systems are available to mechanically process contaminated items. The equipment manufacturer's written IFU must be followed to ensure safety for workers and patients, and the instrument manufacturer's written IFU should be followed to ensure effective cleaning of the instruments. Mechanical cleaning equipment removes soil and microorganisms using an automated cleaning and rinsing process and sometimes incorporates a thermal disinfection or chemical disinfectant process. This equipment should be located in the decontamination department.[4]

Ultrasonic Cleaners

Ultrasonic cleaning systems use high-frequency sound waves to remove particles. The sound creates bubbles on the instrument in the water bath; the bubbles then implode and draw out the tiny particles from the crevices, joints, lumens, and other difficult areas of the instrument. Some units may have connectors for lumens. A more detailed explanation of this method can be obtained from the manufacturer. Ultrasonic cleaners are used for fine cleaning and not for final disinfection or sterilization and should be used only after gross soil has been removed.[4]For the ultrasonic cleaner to be effective, the cleaning solution should be changed before it becomes heavily soiled, which also minimizes the risk of cross-contamination.[4]Thorough rinsing follows to dislodge particles. Follow the ultrasonic cleaners' and instrument manufacturers' written IFU to ensure that the instruments are properly cleaned and not damaged. For effective cleaning, the instrument manufacturer may require multiple ultrasonic cycles. Choose the correct cycle and load the instruments properly, especially if using lumen irrigators; this requires the use of the correct connector.

Washer-Disinfectors and Decontaminators

Washer-disinfectors and decontaminators are used for cleaning and intermediate-level disinfection but not final disinfection or sterilization of soiled reusable utensils, trays, bedpans, urinals, rubber and plastic goods, and simple hard-surfaced rigid surgical instruments such as forceps and clamps. Some units may have lumen irrigators. These units usually come with pumps to dispense an enzyme and detergent with a water temperature up to 180°F (82°C) for washing, a lubricant, and a thermal pure-water rinse up to 194°F (90°C) and a drying phase. The cycles (e.g., time at temperature) may vary from manufacturer to manufacturer, so the equipment manufacturer's and instrument manufacturer's written IFU must be followed to ensure that the instruments are properly cleaned. The correct cycle for

the load contents must be selected and the items must be loaded as required. Never choose a shorter time (e.g., basin cycle) than suggested for instruments to save time, because the items will not be clean.

Cart and Utensil Washers/Disinfectors

This equipment is used for cleaning and low-level disinfection and drying, not final disinfection or sterilization of carts, containers, utensils, beds, and other miscellaneous reusable items. Some units may have a cycle for cleaning and intermediate-level disinfection of simple hard-surfaced rigid surgical instruments such as forceps and clamps. There is a wash, thermal rinse, and drying phase. The cycles (e.g., time at temperature) may vary from manufacturer to manufacturer, so the equipment manufacturer's and instrument manufacturer's written IFU must be followed to ensure that the instruments are properly cleaned. The correct cycle for the load contents must be selected, and the items must be loaded as required.

Washer/Pasteurizer

Although not a sterilization procedure, pasteurization is an acceptable (and cost-effective) cleaning and high-level disinfection alternative for respiratory therapy and anesthesia equipment. Following a precleaning, the equipment uses hot water (150°F to 170°F or 65°C to 77°C) for at least 30 minutes, killing all pathogenic organisms except bacterial spores. The equipment manufacturer's and instrument manufacturer's written IFU should be followed to ensure that the instruments are processed correctly. The temperature of the final rinse should be monitored with an irreversible thermometer or a remote sensing device.[4]

Automatic Endoscope Reprocessors

This equipment is designed to clean and chemically disinfect the scope. A final rinse is usually part of the process. Not all units have a washing cycle, and it should be determined if manual cleaning is required before use. Again, the operator must know if processed items are safe for handling. If the washer does not have a drying cycle, the scopes should be rinsed with isopropyl alcohol, dried with air under pressure, and hung in a storage cabinet so the tip does not touch the bottom of the cabinet. Scopes should not be stored in their original foam-lined container.

The equipment manufacturer's and scope manufacturer's written IFU must be followed to ensure that the instruments are properly processed. The minimum recommended concentration (MRC) or minimum effective concentration (MEC) of the chemical disinfectant should be tested before each use to ensure that the concentration of the active ingredient is adequate.[7] In addition, the printout should be checked at the beginning and end of the cycle to verify that cycle parameters were met, and the printout should be initialed.[7]

Cleaning Verification of Manual and Mechanical Cleaning Processes

Cleaning verification is the final step in the manual cleaning process and includes visual inspection (see *Inspection of Instruments and Other Items* below) for any visible soil and may include the use of magnification. Because visual inspection alone is not sufficient to assess the efficacy of the cleaning process, a commercially available test that detects the presence of organic residues should be considered to monitor the effectiveness of the cleaning process.[4] In AAMI ST79, Annex D discusses user verification of cleaning processes and Table D.1 lists the in-use tests available to assess efficacy of

cleaning of medical devices.[4]AORN recommends that manual cleaning should be evaluated when new types of instruments are reprocessed and periodically at intervals determined by the healthcare facility.[5] Follow the manufacturer's cleaning verification tests as written in the IFU and perform cleaning verification frequently, especially for instruments that are difficult to clean.

Cleaning verification is also important for mechanical cleaning equipment. AAMI ST79 states that mechanical cleaning equipment should be tested upon installation, weekly (preferably daily) during routine use, and after major repairs.[4]All cycles used should be tested when evaluating or changing cleaning chemistry to ensure that the cleaning chemistry and cleaning action is still effective.[4]All cycles used should also be tested after major repairs, which includes replacement of the water pump(s), detergent delivery system, heating system, water delivery system, water treatment system, or computer control, or an upgrade to the software.[4]In AAMI ST79, Annex D discusses user verification of cleaning processes and Table D.2 lists the in-use tests available to assess efficacy of mechanical cleaning equipent.[4]Cleaning verification monitors are available to verify the cleaning efficacy of all the equipment discussed above. This includes the sonic activity of ultrasonic cleaners, the ability of irrigators to clean lumens, the ability of the water in the cart and utensil washers to contact all areas that need to be cleaned, and the overall cleaning efficacy of the equipment.[4]In addition, the water temperature should be monitored because it is a key cleaning parameter. An irreversible thermometer or remote sensing equipment can be used.[4]

Cleaning verification of instruments can occur after manual, ultrasonic, and mechanical cleaning processes to identify failures in the system so corrective action can be taken. The cleaning process must be effective for the disinfection and sterilization process to be effective.[4]AAMI ST79 says that monitoring and documenting the decontamination process parameters is part of a quality system, whether the process is manual or mechanical.[4]

Inspection of Instruments and Other Items

When cleaning and disinfecting have been completed and devices are safe for handling, reprocessed items need to be inspected (see *Cleaning Verification of Manual and Mechanical Cleaning Processes*above). This step may occur in the decontamination area or in the packaging and assembly (clean) area. Some facilities use the decontamination staff for this activity, because any unclean items can quickly be reprocessed. Other facilities prefer the packaging and assembly staff, because the items are inspected for other quality issues before being packaged. A transfer method needs to be established that facilitates the return of unclean items from the clean area to the decontamination area. It is important to note that hand hygiene sinks are not designed to clean and decontaminate reprocessed instruments and should not be used for anything other than hand washing. Next, items need to be inspected for proper function and defects, as well as to ensure that all soil has been removed.[4]The cleaning of orthopedic and neurosurgical instruments pose a significant challenge to SP personnel. Integrity, correct functioning, and the need to replace parts should be addressed at this point. The sharpness of cutting surfaces should be checked. Lighted magnifying glasses should be available at workstations to assist with detailed inspections. Sterilization containers must also be inspected to verify integrity, correct for proper functioning, and replace parts of rigid containers, such as the filters and valves.

PREPARATION AND PACKAGING

Area Design

The preparation and packaging area should be physically separated from the decontamination area.[4] If it is not possible to achieve separation, as could be the case in clinics or office-based facilities, "the preparation area should be thoroughly cleaned and decontaminated before being used for clean preparation and assembly tasks."[4] Beyond the decontamination area, SP requires positive airflow (pushes air out of the work area into adjacent areas or hallways). Many SP areas receive clean linen, such as surgical towels, to be added to sets and packs. The linen sorting and folding process should be in an enclosed space separate from the remainder of the preparation area(s) to reduce the accumulation of lint. The airflow should be a downdraft type with 10 air exchanges per hour.[4] Housekeeping procedures need to take into account the potential for the presence of lint generated from the surgical linen, because lint can transfer from surgical packs to a surgical wound. Once there, it can act as a foreign body and lead to adverse patient reactions.[8] Housekeeping procedures should be the same as those used to clean operating rooms and delivery rooms.[4]

Packaging of Healthcare Facility Prepared Sets or Trays

The SP staff usually places items into predetermined sets or trays (per the facility's instruction sheets [often called the recipe cards], count sheets, tray lists, or computer-generated sheets). Included on these sets or tray lists may be the presence of implantable items that will require the use of a BI process challenge device (BI PCD) in the load. The arrangement of the items or instruments is critical to the sterilization process to maximize contact with the sterilizing agent. The written IFU from the individual instrument manufacturer, and the instructions for the rigid container, and for the wrap should be followed. Only instruments and other items that require the same sterilization process (e.g., type of sterilizer, cycle time, and temperature) should be placed into a set or tray.[9] Instruments and devices must be opened, unlocked, disassembled, and dry. Other items, such as basins, medicine cups, etc. should be inverted so that moisture does not accumulate during the sterilization process. Peel pouches should not be placed inside of sets or trays because they may interfere with sterilization and drying.[4]

Tray liners or other absorbent material may be added, if FDA cleared, for that application and sterilization processs.[4]

When assembling sets or trays, the processor needs to take into consideration the size, weight, design, density of instruments, distribution of mass (density), and composition of the set. Manufacturers of sterilizers, rigid containers, and wraps will note restrictions related to content, weight, and configuration of loads. For ergonomic reasons, instrument sets should not weigh more than 25 pounds.[4] Information and training on packaging and load arrangements should be obtained from manufacturers of sterilizers and packaging, as well as from professional organizations' recommended practices—such as those from AAMI, AORN, and IAHCSMM. It is the responsibility of the staff in SP to follow the IFU, perform product testing, and monitor the sterilization process to determine if the set can be sterilized and dried effectively.[4]

Packaging Materials

Before sterilization, instruments and other items should be packaged to ensure protection during sterilization and to maintain sterility until the device is used. Packaging materials include textile wraps (woven or nonwoven), peel pouches, and rigid containers (metal or plastic). Wrapping products may be single use, disposable (nonwoven), or reusable (woven textile). Peel pouches are preferred when visibility of the item is important or when sterilizing one or more items. Tip guards, holders, or foam sleeves (which must be compatible with the sterilizing agent and validated for that usage by the manufacturer) should be placed over sharp points to prevent damage to the instrument and prevent puncture of the packaging.

The packaging manufacturer's written IFU should be followed. Several performance properties of the packaging materials should be considered, as follows. First, packaging should allow the sterilizing agent to enter and exit the set/pack. The chemical agent needs to be able to penetrate to the interior of the package's content to achieve sterilization. In addition, the packaging material should not retain any residual chemical agent. It is important to follow the sterilizer manufacturer's IFU on type of packaging that can be used for steam and low temperature sterilization processes and labeling of the packaging to ensure that it has been FDA cleared for a specific sterilization process and cycle. It is also important to follow the storage conditions section of the packaging material IFU. "Before use, packaging materials should be held at room temperature (20°C to 23°C [68°F to 73°F]) and at a relative humidity ranging from 30 to 60 percent for minimum of 2 hours."[4]This storage condition is needed to permit adequate steam penetration and superheating, which can result in a steam sterilization process failure. Desiccated packaging material can also result in an EO sterilization process failure.

Second, durability of the packaging is critical, especially when loading and unloading the sterilizing cart. Durability is also important during handling and manipulating during transport and storage. The packaging should be strong enough to withstand normal use in a healthcare setting without tearing or puncturing.

Third, packaging materials should repel moisture and water. Water can allow contamination with microorganisms. Packages should be visually inspected when removed from the sterilizer cart. "If a wet pack is observed, consideration should be given to opening other packs in the questionable load to check for moisture and/or to recalling all items from the load."[4]Refer to Annex P moisture assessment in AAMI ST79 for further assistance in diagnosing and preventing wet packs.[4]

Fourth, the packaging must be made of low-lint material. The presence of lint is troublesome in the SP area because it makes maintaining a clean environment difficult, and, more importantly, lint can collect on surgical instruments and in the surgical incision during surgery. Lint fibers have been associated with postoperative patient complications, such as granulomas, adhesions, and infections.[8]

Finally, ignition resistance is a consideration.[8]Because of the potential hazard for fires in the operating room, materials with low flammability are critical. Manufacturers should provide information on each product's characteristics.

Once the packaging materials have been selected, the SP processor should be shown the proper wrapping and packaging procedures needed to ensure aseptic presentation of sterilized items at the point of use. The correct order and direction of folds and the number of wraps are critical for maintaining sterility and reducing contamination at the site of use. Sterilization indicator tape, not safety pins, paper clips, staples, or other sharp objects, should be used to close woven and nonwoven wraps.[4]

The manufacturers of packaging products' IFU should be followed. AAMI ST79 also provides figures showing proper packaging techniques for textile wraps and peel pouches.[4]

Protective packaging should offer impervious protection from environmental contamination. Sterility maintenance covers (dust covers) are used to protect devices from elements in storage and extend their shelf life if they are going to be "subjected to environmental challenges or multiple handling before use."[4] The 2- to 3-mm-thick plastic bags in various sizes are heat-sealed or self-sealing. The sterilized items are placed in dust covers immediately after cooldown or aeration. Minimal handling is recommended when placing items into dust covers.[4] The use of dust covers has diminished with event-related sterility; however, with items that are rarely used, it might be beneficial.

Peel pouches are an invaluable compact and convenient packaging material for single instruments or small, lightweight, low-profile items such as one or two clamps or Army-Navy instruments. Peel pouches are specific for the type of sterilant used. Excess air should be forced out of the pouch before sealing. Sealing can be done with heat or self-sealing adhesives. Pouches should never be stapled or paper-clipped. Labels can be applied to the pouch, or a permanent marker can be used to write on the plastic side. Writing on the paper side can compromise package integrity. Double-peel pouching is not an acceptable practice unless the peel pouching used has been validated for that use.[4] When double-peel pouching, the inner pouch should fit inside the outer pouch without folding and be positioned so the paper faces paper and plastic faces plastic.[4]

Although much more durable than sterilization wrap, rigid sterilization containers can be damaged by poor care or handling techniques. It is important to follow the rigid container manufacturer's written IFU for cleaning with the appropriate chemical solution and for preventive maintenance. Containers need to be disassembled, cleaned, and inspected after each use for dents or cracks that might compromise the integrity of the seal. Used filters should be discarded. The gaskets should be inspected and replaced if torn or cracked, or if they are no longer soft and pliable. Precut filters should be placed and secured in the filter casing according to the manufacturer's IFU. Some manufacturers have replaced the filter design with a valve or reusable filter. In this case, the valve or reusable filter should be assessed for proper functioning and cleaned according to the manufacturer's IFU.

Product Identification and Traceability

Each package should be labeled with a lot control identifier that lists the sterilizer identification number, the date of sterilization, and the cycle number.[4] "Ideally, every reprocessed medical device, especially an implant, should be fully traceable to the patient on whom it is used or in whom it is implanted; such traceability can be accomplished by recording the sterilizer load identifier on the patient chart or the patient name on the load record."[4] The lot control identifier date can be used for stock rotation. Each package should also be labeled with an expiration statement such as "Contents sterile unless package is opened or damaged. Please check before using."[4]

Inventory Tracking

An essential component of the reprocessing is the inventory of medical devices. This involves a manual stock count or a computer-assisted system. Some facilities use manual methods for this tracking, which requires many people. Other facilities use computer systems capable of scanning tagged or labeled

instruments; their use has greatly improved the efficiency and efficacy of this task. Either system needs to be in place to track items in sets, track items in stock supply, and track items out for repair.

STERILIZATION

Area Design

Sterilizers are located along the processing pathway adjacent to where sets are prepared and assembled, on the "clean" side, away from the decontamination area. The number of air exchanges, temperature, and relative humidity ranges are listed in Table 106-2.[4] The sterilizer manufacturer's written IFU for installation should be followed.

Selection of Sterilization Methods

Selecting the method of sterilization to be used is dependent on the sterilization process validated for use by the instrument manufacturer and provided in the written IFU, turnaround needs, the volume of medical devices to be reprocessed, the compatibility of medical devices with the sterilizing method, exclusion of any instruments and materials, space availability, safety, consideration of the advantages and disadvantages of each method, and cost. An overview of advantages and disadvantages of the most common sterilization methods is available in **31. Cleaning, Disinfection, and Sterilization**. The SP staff is responsible for following the healthcare facility's policies and procedures and the instrument, packaging, and sterilizer manufacturers' written IFU. The sterilizer equipment manual for care and maintenance should also be followed to minimize sterilizer downtime and prevent sterilizer malfunctions.[4]

When operating a sterilizer, the SP staff is responsible for care and maintenance of the sterilizer, loading the sterilizer, choosing the correct sterilization cycle, monitoring the effectiveness of the process and documenting the results, and unloading the sterilizer. This monitoring includes chemical and BIs.

Loading the Sterilizer

It is important to follow the sterilizer, instrument, and packaging manufacturers' IFU. In general, in a steam sterilizer mixed-load, rigid containers or other containment devices and wrapped instrument sets or trays and basins (tilted on edge and oriented the same way) are placed on the shelf below absorbent items such as textile packs containing towels, drapes, or other absorbent materials to prevent the wetting of the absorbent items by condensate. The rigid containers or other containment devices and wrapped instrument sets or trays should always be placed flat to allow for air removal, sterilant penetration, condensate drainage, drying, and keeping instruments in an orderly arrangement.[4]

Containers from different manufacturers should not be stacked because the configurations for air removal and steam penetration may not match.[4] Racks are available to assist in loading peel pouches so they are placed on edge, not flat, with the paper side facing in one direction.[4] The same principles apply to tabletop sterilizers, which are easily overloaded. Ensure that all items in the load have the same recommended sterilization process and cycle parameter.[9]

Selecting the Sterilization Process and Cycle Parameters

It is important to follow the sterilizer, instrument, and container or other packaging manufacturers' written IFU to determine the correct sterilization process and cycle parameters. If there is conflicting information, SP staff should check with the manufacturer of the instrument or other items being sterilized, as it is manufacturer's responsibility to validate the sterilization process recommended in their

IFU.[4,6] The same sterilization process and cycle parameters should be used in any location within the facility that is processing a device. This means required, extended steam sterilization cycles should be used in the operating room (OR) if recommended by the IFU. IUSS cycles (no or reduced drying time) should only be used if recommended in the instrument manufacturer's IFU. Sterilization processes and cycle parameters and original packaging (e.g., loaner trays) should not be changed unless validated by the medical device manufacturer.

Unloading of the Sterilizer and Sterile Storage

Time is required to cool down any heat-sterilized items to prevent condensation from forming when the metal equipment or devices come in contact with room air. The load should remain on the cart until items are adequately cooled to prevent contamination of the items from handling.[4] Because cooling time will vary with the load, temperature-sensing devices are available to determine the internal temperature of the package before removing items from the sterilizer rack to storage. EO sterilized items require aeration time in the sterilizer to remove traces of the gas before they are unloaded. The sterilizer manufacturer's IFU should be consulted for more information on unloading the sterilizer.

During removal from the cart, items should be visually inspected for torn or wet packaging and for external CIs that suggest inadequate processing.[4] Items that are dropped or that have compromised packaging or failed external CIs should not be used; they should be returned to the decontamination area for breakdown and reprocessing.[4] Recall of items can be based on the results of the external CI. See the *Recall* section below. Other items are then placed into sterile storage to await distribution. Items should be stored and distributed in a manner to reduce contamination as described in AAMI ST79.[4]

QUALITY CONTROL

Sterilization process monitoring includes the use of physical monitors, chemical and BIs, and documentation of those results.

Physical Monitors and Bowie-Dick Testing for Equipment Control Monitoring

The sterilization parameters that affect the efficacy of the sterilization process include temperature, exposure times, pressure, vacuum levels, moisture conditions or relative humidity, chemical concentrations, and adequate air removal. Each load's parameters (specific to the type and design of the sterilizer) should be monitored and documented. The SP staff should verify the information provided on the digital printouts, recording charts, displays, or gauges at the end of the cycle by reading and initialing the results.[4] If the physical monitoring results are not correct for the load contents, the load should not be released for use, and the supervisor should be notified to initiate follow-up measures.[4,7,10] Recall of items can be based on the results of the physical monitor. See the *Recall* section below. Do not use sterilizers that do not have recording devices.[4,7,10] Bowie-Dick testing should be done each day, before the first processed load, in each dynamic-air-removal steam sterilizer in all locations in the healthcare facility to detect air leaks, inadequate air removal, inadequate steam penetration, and the presence of noncondensable gases.[4,6] The sterilizer should not be used if the Bowie-Dick test pack does not show a pass. It should be removed from service and repaired.[4] The steam sterilizer and Bowie-Dick test pack IFU should be followed in addition to the information in Section 10 of AAMI ST79.[4]

Chemical Indicators for Exposure, Pack, and Load Control Monitoring

A CI is a device that monitors the presence of one or more of the parameters required for an effective sterilization process or to monitor the sterilizer equipment (e.g., see Bowie-Dick testing under *Physical Monitors and Bowie-Dick Testing for Equipment Control Monitoring).*[4]The device is designed to respond with a characteristic chemical or physical change to one or more of the physical conditions within the sterilizing chamber.[4]CIs are intended to detect potential sterilization process failures that could result from incorrect packaging, incorrect loading of the sterilizer, or malfunctions of the sterilizer. The "pass" response of a CI does not prove that the item accompanied by the indicator is necessarily sterile. AAMI ST79, ST41, and ST58 have defined six classes of CIs: Class 1 (process indicators), Class 2 (Bowie-Dick tests), Class 3 (single-variable indicators), Class 4 (multivariable indicators), Class 5 (integrating indicators), and Class 6 (emulating indicators). A review of the classes of CIs for steam sterilization and their application for monitoring is noted in Table 106-3.

Table 106-3 Classes of Chemical Indicators

Class	Description	Use
Class 1	Process indicators	Process indicators are intended for use with individual units (e.g., packs or containers) to indicate that the unit has been directly exposed to the sterilization process and to distinguish between processed and unprocessed units. They are designed to react to one or more of the critical process variables.**4**,**7**,**10** These types of indicators are called external CIs and should be used on the outside of each package unless the internal CI is visible. Examples are sterilization indicator tape, an indicator label, or printed legend as seen on the outside of peel pouches, and load cards.**4**,**6**,**10**
Class 2	Indicators for use in specific tests	Class 2 indicators are intended for use in specific test procedures as defined in relevant sterilizer or sterilization standards.**4**An example of this type of indicator would be the Bowie-Dick test that is designed to test for air removal in dynamic-air-removal steam sterilizers.**4**
Class 3	Single-variable indicators	A single-variable indicator is designed to react to one of the critical variables and is intended to indicate exposure to a sterilization process at a stated value (SV) of the chosen variable.**4**,**7**,**10** An example of a single-variable indicator is a temperature tube that contains a chemical pellet that melts at a specific temperature. Single-variable indicators may be used as internal CIs for pack control monitoring but would not provide as much information as a Class 4, Class 5, or Class 6.**4**,**6**,**7**,**10**
Class 4	Multivariable indicators	A multivariable indicator is designed to react to two or more of the critical variables and is intended to indicate exposure to a sterilization cycle at SVs of the chosen variables.**4**,**7**,**10** These CIs are usually paper strips printed with a color change CI and are used as internal chemicals for pack control monitoring.**4**,**6**,**7**,**10**
Class 5	Integrating indicators	Integrating indicators are designed to react to all critical process variables. The SVs are generated to be equivalent to or to exceed the performance requirements published in the ANSI/AAMI/ISO 11138 series for BIs.**4**,**7**,**10** The results of Class 5 integrating indicators are more closely aligned with BI performance and are the most accurate of the internal CIs but do not replace the use of BIs.**5**,**7** Class 5 integrating indicators may be used as internal CIs for pack control monitoring.**4**,**6**,**10**Class 5 CIs may be used as an additional monitoring tool in process challenge packs to monitor nonimplant loads.**4**,**6**The CI should be in the BI process challenge device used to monitor implant loads.

Class 6	Emulating indicators	Emulating indicators are cycle verification indicators that are designed to react to all critical variables for specified sterilization cycles.[4,7,10]The SVs are generated from the critical variables of the specified sterilization process.[4,7,10] Class 6 CIs may be used as internal CIs for pack control monitoring.[4,6]Class 6 CIs may be used as an additional monitoring tool in process challenge packs to monitor non-implant loads.[4,6]This CI cannot replace the use of a Class 5 CI in the BI process challenge device used to monitor implant loads or the use of a BI.[5,7]

CIs should be used outside of each healthcare-prepared package, tray, or containment device unless the internal CI is visible. These external CIs are used for exposure control to determine if the item has been processed. The external CI should be read when unloading the sterilizer, dispensing or issuing the item for use, and before the item is opened in the OR.[4,6,7]If the external CI suggests inadequate processing, the package should not be used.

CIs should also be used inside of each healthcare-prepared package, tray, or containment device in the area considered the most challenging to sterilant penetration.[4,6,7,10]The containment device manufacturer should be consulted about where to place the internal CIs.[4,7,10]These internal CIs are used for pack control to determine that the sterilant penetrated each package. The internal CI should be read before the package is placed on the sterile field.[11]If the internal CI suggests inadequate processing, the package should not be used and should be returned to SP, and the supervisor should be informed to determine if the load should be recalled (see *Recall*section below).[4,6,10]

Class 5 and Class 6 CIs may also be used inside PCDs as an additional monitor tool for nonimplant loads.[4,6]Class 5 CIs should be used inside of the BI PCDs to monitor implant loads and can be used in defined emergency situations to release implants (see *Biological Indicators for Load Control Monitoring*section below).[4,6]

More details about the use of CIs can be found in Section 10 of AAMI ST79 and ST41 and Section 9 of ST58. Always follow the CI manufacturer's written IFU for proper usage, interpretation of results, and storage conditions.

BIOLOGICAL INDICATORS FOR LOAD CONTROL MONITORING

BIs consist of a standardized, viable population of microorganisms (usually bacterial spores) known to be resistant to the sterilization process being monitored. BIs are the only process indicators that directly monitor the lethality of a given sterilization process and they cannot be replaced by the use of either Class 5 or Class 6 CIs.[4,6]Spores used to monitor a sterilization process have demonstrated resistance to the sterilizing agent and are more resistant than the bioburden found on medical devices or instruments. *Bacillus atrophaeus*spores are used to monitor EO and dry heat sterilization processes, and *Geobacillus stearothermophilus*spores are used to monitor steam sterilization, hydrogen peroxide with or without gas plasma, and ozone sterilization processes.[4,6]BI monitoring is not required for the liquid peracetic acid processor, but a spore strip containing *G. steaorthermophilus*spores is available.[6,7]Follow the BI manufacturer's IFU to determine which BI and PCD to use to monitor a specific sterilization process and cycle. Monitoring includes use of the positive control, as well as records of the incubation temperatures and readout time.[4]AAMI ST79 describes the types of BI PCDs and procedures to use for routine and

qualification testing for steam sterilizers.[4]AAMI ST41 describes the same information for EO sterilizers.[10]

Because there are no standardized BI PCDs for routine and qualification testing for other low-temperature sterilization processes, AAMI ST58 describes the information that should be obtained from the sterilizer and BI manufacturer for preparing and running a BI PCD for routine and qualification testing.[7]All these documents also describe how to run a positive control from the same lot number in each incubator or autoreader each day a test BI is incubated.

Steam sterilizers should be routinely tested at least weekly—preferable daily—with a BI PCD.[4,6]Sterilizer qualification testing is done using a BI PCD after sterilizer installation and relocation, sterilizer malfunctions, and sterilization process failures.[4,6]See Section 10 in AAMI ST79 for more details on how to perform routine sterilizer efficacy and qualification testing of steam sterilizers.[4]

There are two types of BI PCDs for EO testing. One is for routine sterilizer efficacy testing, which should be done in each load and to test the sterilizer after a sterilization process failure, malfunction, or major repair.[10]The second BI PCD is for qualification testing, which is done after sterilizer installation, relocation, or major redesign.[11]See Section 10 of AAMI ST41 for more details on how to perform routine sterilizer efficacy and qualification testing of EO sterilizers.[10]

Hydrogen peroxide with or without plasma and ozone sterilizers should be tested at least daily, but preferably in every sterilization cycle with a BI PCD (as should EO sterilizers).[6,7]A BI PCD should also be used for sterilizer qualification testing during initial installation of the sterilizer and after relocation, major repairs or malfunctions of the sterilizer, and sterilization process failures.[6,7]Because there are no AAMI standardized BI PCDs for these low-temperature gaseous chemical sterilizers for either routine or qualification testing, the sterilizer manufacturer should be consulted for material selection, assembly, and placement.[6,7]Section 9 of AAMI ST58 does provide some basic information about this testing that should also be accessed for more information.[7]

Each load of implants should be monitored with a BI PCD, and the load should be quarantined until the BI results are available.[4,6,7]For steam sterilizers, a Class 5 integrating indicator should also be included in the BI PCD for early release of implants in defined emergency situations.[4,6]"Releasing implants before the BI results are known is unacceptable and should be the exception, not the rule."[4,7]Annex L of AAMI ST79 and Annex M of AAMI ST58 provide an implant log (see Figure 106-3) and exception form to use for documentation of the early release of implants.[4,7]The log and exception form can be used to reduce the frequency of emergency release of implantable items.[4,7]The implant-monitoring documentation should be fully traceable to the patient.[4,6,7]

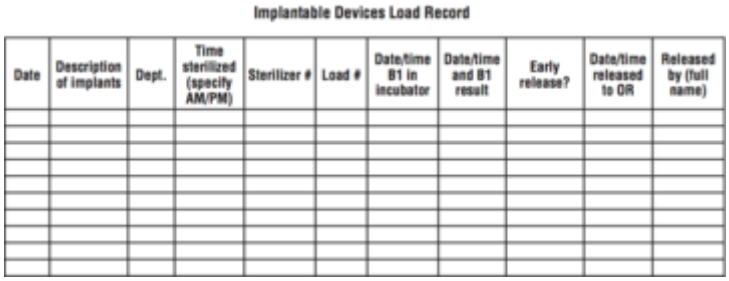
Monitoring of every load and quarantining loads until the BI result is known is a method to reduce the risk and cost of healthcare-associated infections (HAIs). This method shows the load was effectively sterilized before it was released for use, and it provides a method for identifying a failure in the sterilization process before the sterilized contents are used in patient treatment. This also reduces the cost and impact of a recall and ensures that all implants are monitored.

If a BI is positive, the load should not be released. If the load has already been released, a recall should take place.[4] The cause of the positive result should be investigated. If the positive result is due to the need for major repairs to the sterilizer, sterilizer qualification testing must be performed before the sterilizer is put back into service.[4]

Recalls

AAMI ST79 addresses recalls in Section 10 under "Action to take when BIs, CIs, or physical monitors indicate a failure."[4] In Section 10 of ST79 is Figure 12, which shows a decision tree for conducting investigations of steam sterilization process failures, which indicate when a recall is needed. Table 8 shows a checklist for identifying reasons for steam sterilization process failures. A recall is not needed if the cause of the failure is immediately identifiable, which is usually the result of an operator error and confined only to one load.[4] For example, an operator error that is immediately identifiable is running the wrong sterilization cycle for the load contents. At that point only the error needs to be corrected and the load reprocessed. If the error is not immediately identifiable, which will be the case in the vast majority of sterilization process failures, actions to take include recalling all items that have been processed since the last negative BI. This action would be taken if the BI, CI, or physical monitor identified a problem. The advantage of every-load monitoring with a BI and quarantining until the BI results are known is that only the one load in question is involved, so there is no patient involvement. The decision tree also indicates when qualification testing with BI PCDs is needed.

The Section on Action to take when BIs, CIs, or physical monitors indicate a failure in AAMI ST79 can be used to assist in developing a written policy and procedure to address who, when, and how to recall reprocessed items. In addition, the policy may include compliance components of the Safe Medical Device Act if failure is noted in the reuse of reprocessed items. At a minimum, a log of items within the sterilized load should be reviewed along with the monitoring results, unused items in the load retrieved for reprocessing, a root cause of the sterilization process failure identified, required sterilizer testing completed, and surveillance of involved patients initiated. The recall process is often collaborative and should include the IP, risk manager, surgical services manager, and the surgeon or the attending physician for the involved patients. The same recall process can be used for low-temperature sterilization processes also.[4,10] AAMI ST58 also has in Section 9 information on actions to take if a BI test is positive.[7] The information in AAMI ST79 Figure 12 could also be used for low-temperature sterilization process failures.[4]



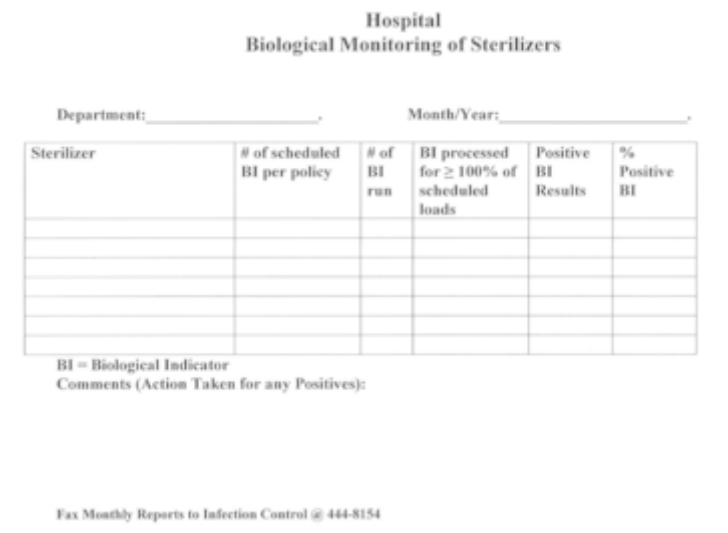
Documentation/Recordkeeping

Most regulatory and professional agencies and organizations recommend records be kept of the sterilization cycles. Each item or package should be labeled with a lot control identifier which includes the sterilizer identification number or code, the date of sterilization, and the cycle number.[4,7,10] For each sterilization cycle, the SP staff should document the lot number; date; time; contents of load including quantity, department, and a specific description of the items; exposure time and temperature; operator's name or initials; results of BI testing and Bowie-Dick testing, if applicable; response of the CI placed in the PCD; and any reports of inconclusive or nonresponsive CIs found later in the load.[4,7] Aeration information would be included for EO processed loads.[10] As discussed before, any equipment maintenance, repairs, and calibration must be documented for each sterilizer. This will help assist in determining if a major or minor repair was made to a sterilizer after a sterilization process failure

occurred. The SP staff also needs to document when the sterilizers were cleaned or other routine maintenance was performed according to the sterilizer manufacturer's written recommendations for maintenance and cleaning. Digitization of this documentation process will allow quicker access to load information for troubleshooting.[4]Healthcare facilities should follow their facility's policy for the length of time that records must be kept.

Reporting Results of Monitoring

In accordance with TJC standards, the hospital implements infection prevention activities when cleaning, disinfecting, sterilizing, and storing medical equipment, devices, and supplies. The hospital's infection prevention committee or authority should routinely receive reports of the monitoring of the sterilization process. The report should include whether or not testing was conducted according to policy (i.e., daily, every load with implants) as well as the number of positive results and what actions were taken, and how many times implants were released before the BI results were known. This information can be included in infection prevention committee minutes. An example of an implantable device log is shown in Figure 106-3, and an example of a monthly biological monitoring log is shown in Figure 106-4.



Implantable Devices Load Record

Date	Description of implants	Dept.	Time sterilized (specify AM/PM)	Sterilizer #	Load #	Date/time BI in incubator	Date/time and BI result	Early release?	Date/time released to OR	Released by (full name)

Immediate-Use Steam Sterilization

IUSS (formerly called flash sterilization) is a sterilization process designed for the cleaning, steam sterilization, and delivery of patient care items for immediate use.[4]Originally instruments were unwrapped and processed for emergencies when a single instrument was dropped on the floor, but flash sterilization gained wider usage in situations in which the OR schedule did not permit reprocessing in SP. AAMI, the AORN, and TJC do not recommend the use of IUSS because IUSS may be associated with increased risk of infection to patients.[4,11]This is because time constraints to reprocess more quickly lead to pressure on personnel that could result in shortcuts such as eliminating or modifying one or more of the steps in the cleaning, packaging, and sterilization process recommended by the instrument manufacturer's IFU.[6]The result is instruments that are not adequately cleaned or sterilized, and the only time saved is elimination or shortening of the dry cycle. IUSS should not be used as a substitute for sufficient instrument inventory.[6]

To use IUSS instruments, the items to be sterilized need to be decontaminated (cleaned and inspected) in an environment that will minimize the transmission of organisms, just as they would in SP.[4,6]The OR should have the equipment available for manual and/or mechanical cleaning, cleaning solutions, tools such as brushes, water quality, rigid sterilization containers/packaging, and sterilizers and cycles, as does SP and as required in the instrument manufacturer's IFU. The area should be separated from clean areas. To prevent contamination and injury to staff, PPE should be worn when cleaning items. Use the cleaning solutions recommended by the manufacturer; never use antiseptic (hand scrub products or house cleaning products) to clean surgical instruments. Procedures for cleaning soiled instruments should be the same as those used in the SP decontamination area. Cleaning is the most critical step in IUSS and is often the step that is shortened or done incorrectly. The same sterilization process and cycle should be used in the OR as in SP that will include the use of standard and extended cycles. IUSS cycles (no or reduced drying time) should only be used if recommended in the instrument manufacturer's IFU.

To prevent contamination of the wet instruments during transfer to the sterile field, rigid sterilization containers or other packaging or wrapping materials that are labeled for IUSS should be used.[4,6] Because the packaging is wet, packages should be immediately opened and the content used.[7]Do not store these items for later use or hold for the next procedure.[6]

The IUSS process should be monitored as described in the *Quality Control*section above. AAMI ST79 in Section 10 describes how to prepare BI PCDs and perform routine and qualification testing of IUSS.[4] AORN states that a Class 5 or Class 6 CI should be used with each sterilization container or tray used for IUSS.[6]Bowie-Dick tests need to be run in dynamic-air-removal steam sterilizers and the cycles need to be documented as described in the *Documentation/Recordkeeping*section with the addition of the reason for IUSS. This information can be used to decrease the use of IUSS for process improvement as required by TJC, AAMI, AORN, and HICPAC. IUSS should not be used for implantable devices except in cases of a defined emergency because of the increased risk of SSIs.[4,6,12]Every implant should be fully traceable to the patient.[4,6]

LOANER INSTRUMENTS

Written policies and procedures should address the acquisition, responsibility, accountability, and disposition of loaner instruments. IAHCSMM provides on its website *Position Paper on the Management of Loaner Instruments and a Sample Policy & Procedure for Loaner Instrumentation,*which provides information to assist in developing a loaner instrument policy and procedure.[13]These documents discuss the responsibilities of the OR, sales representative, and central sterile supply department or SP area before and after the instruments arrive. This takes planning to ensure that instruments arrive in time for in-servicing of OR and SP staff, processing according to the instrument manufacturer's IFU, quarantining the implants until the BI result is available, and avoiding the use of IUSS.[6,13]IAHCSMM recommends that loaner trays arrive at the healthcare facility at least two business days prior to the scheduled case and that all first-time vendor-loaned sets arrive three business days prior to the scheduled procedure to allow adequate time for training, inspecting, and processing. If a shorter delivery time is accepted, then shortcuts may be taken, implants may be released before the BI results are known, and IUSS may be used with a shorter-than-required cleaning procedure and sterilization process.[6]AORN states that "Late

receipt of loaned instruments should not be used to justify IUSS" and also provides some information to assist in developing a loaner instrument policy and procedure.[6]

MANAGING ITEMS CONTAMINATED WITH PRIONS

Transmissible spongiform encephalopathies (TSEs) are degenerative, invariably fatal brain diseases that occur in humans and certain animal species. They are caused by an infectious agent known as a prion (see **73. Creutzfeldt-Jakob Disease and Other Prion Diseases**for additional information on TSEs). The most common TSE (80 to 90 percent) is Creutzfeldt-Jakob disease (CJD).[14]TSEs are not known to be spread by person-to-person contact. Reports indicate that TSEs have been spread by exposure to infectious material from human cadaver tissue and organs, dura and cornea homografts, and contaminated neurosurgical instruments.[14]Prions are resistant to routine disinfection and sterilization methods. In 2000, two separate incidents involving patients resulted in a Joint Commission Sentinel Event Alert (June 2001) and a more recent update in September 2013. Investigations found that the diagnosis of CJD was made following surgical procedures, and the instruments were reprocessed and sterilized by routine methods. The possibility of prion transmission to subsequent surgical patients on whom those instruments were used was a concern.[15]

Because prions are resistant to routine disinfection and sterilization methods, special procedures for TSE and CJD cases are needed. Surgical and SP staff need to be knowledgeable about proper procedures for handling, cleaning, decontaminating, storing, and disposing of used surgical instruments, as well as how to manage the contaminated environment. Determining the best method for handling a suspected or known TSE or CJD case should be based on the infectivity level of the tissue and the items used. Although cerebrospinal fluid is listed as having low infectivity, it is recommended that instruments contaminated with cerebrospinal fluid be treated as highly infectious items.[14]

Detailed information on how to manage and reprocess contaminated items can be found in **73. Creutzfeldt-Jakob Disease and Other Prion Diseases**.

STORAGE AND SHELF LIFE

Physical storage restrictions are recommended to support an environment that is conducive to maintaining the sterility of reprocessed items. Sterilized items should be stored as follows:

1. 18 inches below the ceiling or the sprinkler head or according to the fire code
2. 8 to 10 inches from the floor
3. At least 2 inches from an outside wall
4. Away from sprinklers and air vents
5. Open rack storage should have a solid bottom to prevent soiling or contamination from the floor during housekeeping
6. Position packages so they are not crushed, bent, compressed, or punctured
7. Store heavy trays/containers on middle shelves but not stacked
8. In areas of limited traffic
9. Clean workroom or clean holding area(s): airflow must be positive pressure with respect to surrounding areas with a minimum of four air exchanges per hour.**16**In an area with controlled temperature and humidity (approximately 24°C [75°F], relative humidity not to exceed 70 percent).
10. Soiled workroom or soiled holding area(s): airflow must be negative pressure with respect to surrounding areas with a minimum of 10 air exchanges per hour.

11. The first item in is the first item out (first in, first out [FIFO]). Items should be rotated. Place newer items in the back part of the area where they are stored.
12. Consideration should be given to storage that will minimize the collection of dust on surfaces.
13. Outside shipping containers and corrugated cartons should not be used as containers.[4]

Items should not be stored under sinks or under exposed water or sewer pipes. Windowsills should be avoided. Closed or covered cabinets are preferred. Open shelving may be used if the area has limited access and monitored ventilation and is frequently cleaned and disinfected.[6]

Event-Related Sterility

Shelf life is event related. With event-related sterility, items are considered sterile unless the integrity of the packaging is compromised (i.e., torn, soiled, wet, or showing evidence of tampering). Conditions that may alter the integrity of the packaging may include the following:

1. Environmental sources of contamination (e.g., moisture, vermin, and air movement associated with traffic)
2. The barrier properties of the packaging material (e.g., the integrity of its seals and its resistance to tearing)
3. Storage and distribution practices (e.g., open versus closed shelving and transport)
4. nventory control (e.g., realistic standards and stock rotation)
5. Frequency of handling between distribution and the user

DISTRIBUTION

Care should be taken when handling supplies to avoid dragging, sliding, crushing, bending, compressing, or puncturing the packaging or otherwise compromising the sterility of the contents.[4]The integrity and labeling of each package should be visually inspected, including the external CI, before issuing.

Reprocessed, sterilized items should be transferred in covered or enclosed carts with solid bottoms to prevent or reduce environmental contamination.[4]Items should be arranged to prevent crushing, bending, or compression. Carts and reusable covers should be cleaned, disinfected, and thoroughly dried after each use.[5]Outside shipping containers or corrugated cardboard for distribution or storage are unacceptable.[4]

For transportation of sterile items from an off-site distribution point or commercial reprocessor, sterile supplies should be kept separated from contaminated items.[4]Transporting containers should be designed to prevent compromising sterility; they must offer protection from moisture and condensation, insects, vermin, dust, and dirt. The design of the containers should allow easy loading and unloading without contaminating or damaging the packaging and its contents. The containers need to be secure within the transporting vehicle. High humidity or extreme temperature changes need to be considered to manage condensation on or within the reprocessed trays during transportation.

Conclusions

SP is most often the department that is responsible for the reprocessing and sterilizing of instrumentation and medical devices. The process involves handling, collection, transporting, sorting, disassembling, cleaning, disinfection, inspecting, packaging, sterilizing, storing, and distributing reprocessed items. If other areas or departments assume the responsibility for reprocessing their own equipment, it is important that they meet the same standards of practice as SP. This chapter has offered an introduction to the processes that are conducted in SP and provides references and resources regarding published recommended practice, standards, and guidelines. These recommended practices, standards, and guidelines should be available and up-to-date for use in writing policies and procedures and answering specific questions. Every infection prevention department and SP area should have an up-to-date copy of AAMI ST79 *Comprehensive Guide to Steam Sterilization and Sterility Assurance in Healthcare Facilities,*AAMI ST58 *Chemical Sterilization and High-level Disinfection in Healthcare Facilities*, AORN *Perioperative Standards and Recommended Practices*, and the CDC *Guideline for Disinfection and Sterilization in Healthcare Facilities.*[4,7,6,12]

It is essential for employee and patient safety to follow the manufacturer's IFU for the operation of cleaning and sterilizing equipment, the reprocessing of instruments and medical devices, the concentration and use of chemical solutions and disinfectants, and the appropriate use of PPE. Any deviation from the instrument or medical device manufacturers' IFU related to cleaning, packaging, loading, and sterilization could result in an ineffective process and an SSI or other adverse outcome. Results of monitoring of processes and outcomes should be reported to the infection prevention committee or authority and ongoing education, competency testing, and certification for staff is critical to achieve desired outcomes. The IP plays a critical role in the successful achievement of these outcomes and can serve as a valuable resource to the SP areas.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Environmental Services

Author(s): Teresa Chou, MPH, MS, RN, CIC
Manager, Epidemiology and Infection Prevention and Control

Advocate Illinois Masonic Medical Center
Chicago, IL

Published: October 3, 2014

Abstract

There is increasing evidence that the healthcare environment is an important source of healthcare-associated infections. Every facility must thoroughly clean its environment to prevent it from developing into a reservoir for pathogens. The cleaning needs vary by facility and are assessed by a team of experts. These experts are responsible for providing leadership, establishing effective cleaning protocols, preparing regular cleaning schedules, writing policies and procedures, selecting the appropriate cleaning agents and equipment, and hiring and training staff. They are also prepared to address unexpected situations such as outbreaks, natural disasters, back orders on supplies, unavailability of equipment, and staff shortages. Proper education and training of environmental services personnel are critical components of an effective program. Staff must be educated and trained upon hire, at regular intervals thereafter, and as needed. Programs should be developed to assess the efficacy of the environmental services activities. Even when performance improvement measures are outstanding, there is always room for improvement. Patients, visitors, and personnel expect and deserve a clean environment.

This chapter addresses hand hygiene, disinfection, bloodborne pathogen exposure, laundry and linen, and waste management practices as applicable to environmental services. For more in-depth discussion of these topics, please refer to their respective chapters in this Text.

Key Concepts

- To properly maintain their environments, healthcare facilities must adhere to federal, state, and local regulations and should follow guidelines established by the Centers for Disease Control and Prevention and professional organizations.
- Each healthcare institution must establish written policies and procedures for cleaning. These policies and procedures must meet regulatory requirements and published standards and recommendations.

- Environmental surfaces are divided into two categories—those with minimal hand contact such as floors and ceilings and those with frequent hand contact (high-touch surfaces).[1]
- High-touch surfaces may be potential reservoirs for microorganisms. These surfaces need to be cleaned more frequently because contact with them may easily lead to cross-transmission of infection.
- Items or surfaces that are less frequently handled may not need to be cleaned as often. Because they experience fewer contacts, they are less likely to be sources of infection.
- To prevent the dispersal of dust, cleaning activities should be conducted with minimal turbulence.
- Individuals responsible for selecting, purchasing, and/or educating others on the use of cleaning products should have a thorough understanding of the terminology and should be knowledgeable about the efficacies and intended uses of different chemical agents.
- Environmental services directors, managers, and supervisors, in conjunction with infection preventionists and other healthcare professionals, determine when personal protective equipment is necessary, write guidelines for its use, and select and purchase appropriate supplies.
- Biohazardous and nonbiohazardous waste must be separated. If both types of waste are inadvertently mixed, the nonbiohazardous waste is considered biohazardous.
- Environmental services address pest control. If there are no experts within the facility, contract licensed professionals should be hired to handle toxic pesticides.

Background

Accumulation of dust, soil, and microbial contaminants on environmental surfaces in healthcare facilities is not only aesthetically displeasing, but evidence indicates that it also plays a major role in the spread of healthcare-associated infections (HAIs). Studies have shown that many microorganisms survive on surfaces for long periods of time. For example, *Staphylococcus aureus,* including methicillin-resistant *S. aureus* (MRSA), survives more than 12 months; *Enterococcus,* including vancomycin-resistant enterococci (VRE), lives more than 46 months; *Clostridium difficile* persists more than 5 months; and norovirus resides more than 2 weeks. Among the hardy Gram-negative bacilli, *Acinetobacter* and *Pseudomonas aeruginosa* have been isolated from the environment 11 and 16 months later, respectively, and *Klebsiella* has lasted more than 30 months.[2]

Contact with contaminated surfaces easily leads to cross-transmission of microorganisms between people and the environment.[3]The hands of healthcare personnel (HCP) become contaminated while providing care to a colonized or infected patient. HCP then touch and contaminate the inanimate environment surrounding the patient. Patients also spread their flora on surfaces that they contact. If the surfaces are not properly cleaned, the organisms can live on them for long periods of time. When subsequent HCP, patients, and visitors come into contact with the contaminated surfaces, they can acquire the microbes and pass them on to others, contaminating more surfaces. Susceptible individuals can become colonized and/or infected.

Hand hygiene plays an important role in preventing cross-contamination, and maintaining a clean and healthy environment is equally important.[4]Effective and efficient cleaning methods and schedules are necessary to ensure clean and healthy environments in healthcare facilities.

Basic Principles

Regulatory Requirements and Guidelines

Regulatory requirements for maintaining the environment in healthcare facilities are best summarized by Occupational Safety and Health Administration (OSHA):

Employers ensure that the worksite is maintained in a clean and sanitary condition. The employer determines and implements appropriate written schedules for cleaning and methods of decontamination based upon the location within the facility and services provided (patient care, food preparation, offices, mechanical rooms), types of surface to be cleaned (metal, impervious, or cloth), and degree and type of soilage (i.e., blood and body fluids or dirt and dust).[5]

It is mandatory to adhere to federal, state, and local regulations about the care of the environment. Healthcare facilities must also follow regulations addressing chemical, physical, and biological safety, as well as ergonomics. Rules vary by state and municipality.

Nonregulatory agencies such as the Centers for Disease Control and Prevention (CDC), Association for Professionals in Infection Control and Epidemiology (APIC), the Association for Healthcare Environment (AHE), and Association of periOperative Registered Nurses (AORN) provide environmental cleaning guidelines. Relevant CDC publications include *Guidelines for Environmental Infection Control in Healthcare Facilities*[1]and *Guideline for Disinfection and Sterilization in Healthcare Facilities.*[6]AHE issued *Practice Guidance for Healthcare Environmental Cleaning.*[7]AORN addresses cleaning recommendations for operating rooms in *Perioperative Standards and Recommended Practices.*[8]Because these recommendations are often based on existing scientific data, theoretical rationale, applicability, and economics, regulatory surveyors and inspectors often regard them as standards that must be followed.

Cleaning Principles

The key to cleaning and disinfecting environmental surfaces is the use of friction to physically remove visible dirt, organic material, and debris, thereby removing microorganisms.

High-touch and Other Surfaces

The cleaning of environmental surfaces is divided into two categories based on how frequently these items or surfaces are touched and the associated risk of infection transmission. High-touch surfaces or items need to be cleaned frequently because of the high degree of handling and the risk of cross-transmission of infection. Surfaces and items that do not need to be cleaned as frequently are those that are handled less often and are less likely to be sources of infection.[1,6]

High-touch items requiring frequent cleaning include, but are not limited to, medical equipment knobs or handles (e.g., knobs or handles on x-ray machines, cardiac monitors), blood pressure cuffs, bedrails, handheld television controls, nurse call lights, doorknobs, light switches, telephones, and computer keyboards. Many of these surfaces, such as controls on medical equipment, are cleaned after each patient use. The manufacturer's recommended procedures and chemicals for cleaning these surfaces must be followed. Nonadherence with the manufacturer's instructions and using inappropriate cleaning agents may result in damage to the equipment and invalidation of warranties.[9]For example, alcohol is a superb disinfectant but may blur the plastic viewing window of monitors and/or remove labels surrounding knobs. When asked, most manufacturers will provide a list of cleaning agents that will not harm their products.

Alternatively, surfaces such as floors, walls, window curtains, lights, and ventilation grilles usually need less frequent cleaning. Facilities should ensure these surfaces are cleaned routinely by establishing a schedule, creating and following procedures, and using effective cleaning agents. These surfaces must also be cleaned immediately when visibly soiled. It is important to note that cleaning procedures and cleaning agents used for environmental surfaces usually differ from those used for cleaning patient care equipment and instruments.[9]As stated, it is important to adhere to the manufacturer's recommendations.

Patient Zone

There are two zones of care—the patient zone and the healthcare zone.[10]The patient zone consists of the patient and his/her immediate surroundings. Many high-touch surfaces are within the patient zone. For example, in a patient room, the patient zone would be the patient, the patient's bed, and the surrounding high-touch surfaces. The patient zone can quickly become heavily soiled with the patient's flora. If the patient zone is not properly cleaned, the contaminated surfaces can be a reservoir of microorganisms that are subsequently transmitted to the next individual occupying or contacting that zone. At the same time, organisms outside of a patient's zone are foreign and may be potentially harmful if introduced into the zone.

All other areas outside the patient zone fall into the healthcare zone. This includes other surfaces and other patients and their individual patient zones.

Cleaning Procedures

Cleaning schedules and procedures progress from the least soiled areas to the most soiled (patient zone) and from high surfaces to low ones. Routine cleaning is necessary to maintain a basic standard of cleanliness. Procedures must be effective, consistent, and thorough.

Dust contains fungal spores, such as *Aspergillus*, which may cause fatal infections, especially in immunosuppressed individuals.[11]Therefore, it is important to minimize air turbulence and dispersal of dust when cleaning. Environmental services (EVS) personnel should partner with nursing staff to move immunosuppressed patients away from dust-creating activities. Dust-creating activities include dusting, vacuuming, and waxing and buffing floors. When the duster is dampened, treated with an absorbent chemical, or composed of microfiber, spores adhere to the fabric. High-efficiency particulate air (HEPA) filters in vacuum cleaners collect the dust produced by the machines. If the activity is outside the patient's room, EVS should close the door to the patient's room prior to starting.

Cleaning methods and procedures vary among healthcare settings. Therefore, each institution must establish written policies and procedures. A multidisciplinary approach is recommended because cleaning of the environment involves everyone within the facility. The multidisciplinary team should include EVS, infection prevention and control, nursing, administration, clinical engineering, facilities, materials management, pharmacy, information systems, and food services. Among the team members, EVS and infection preventionists (IPs) will most likely form the strongest partnership. IPs can help educate EVS personnel and other staff, offer advice on cleaning procedures and schedules, provide expertise on cleaning agents, assist in writing policies and procedures, and participate in performance improvement activities. An IP must know the facility's EVS cleaning procedures and schedules, assist in selecting disinfectants used, help review and revise written policies and procedures, and collaborate on quality improvement activities.

Every facility should also develop performance improvement activities to measure the effectiveness of its cleaning program.

Cleaning Agents

EVS, IPs, and other individuals responsible for selecting, purchasing, and/or educating others on the use of cleaning products should have a thorough understanding of the differences between and the uses of these chemicals. These individuals should also know the relevant terminology (see Appendix) and understand the following issues:

1. Definitions of the terms cleaning, sanitization, disinfection, and sterilization
2. Definitions of soap, antiseptic, disinfectant, sterilant, and sanitizer
3. Differences among the types and uses of antiseptics
4. Differences among the types and uses of disinfectants, including sporicidal disinfectants[12]
5. Differences between disinfectants, disinfectant-detergents, and detergents or cleaning agents containing no antimicrobial properties
6. Manufacturer's specification for use, including dilution and contact time
7. Difference between Environmental Protection Agency (EPA)- and Food and Drug Administration (FDA)-registered products

Disinfectants

Disinfectants are divided into low, intermediate, and high levels.[6]Low-level disinfectants kill most vegetative bacteria, some fungi, and some viruses within the contact time stipulated by the manufacturer. In addition to vegetative bacteria, intermediate-level disinfectants kill hardier organisms such as mycobacteria, most fungi, most viruses, and some spores. High-level disinfectants kill spores as well as all other forms of microorganisms. The action time and spectrum of disinfectants vary. Detergents have no antimicrobial claims. (See **31. Cleaning, Disinfection, and Sterilization** for additional information.)

In general, low- and intermediate-level disinfectants are used for cleaning surfaces and are reviewed and registered with the EPA, whereas high-level disinfectants, sterilants for medical equipment, and antiseptics are evaluated and approved by the FDA.[1]Registration numbers are labeled on the manufacturer's containers of each product. Registered disinfectants are found on the EPA website.[12,13]

There is a debate about whether to use detergents or disinfectants on environmental surfaces. Detergents are more environmentally friendly, not toxic, produce less offensive odors, are unlikely to trigger adverse respiratory reactions, and cost less than disinfectants. Studies show that floors cleaned with a detergent do not increase the risk of HAIs.[6]Unfortunately, detergents do not effectively remove microorganisms from surfaces. Microorganisms on horizontal surfaces may then easily be transmitted to patients and other surfaces via the hands of HCP and visitors. Detergent solutions can also become easily contaminated. Therefore, the CDC recommends using disinfectants for cleaning horizontal surfaces—especially high-touch surfaces—in patient areas, on medical equipment, in isolation rooms, and during outbreaks. Detergents may be used on floors, except in isolation rooms. Using a variety of cleaning agents to clean different surfaces (such as disinfectants for bedside surfaces and detergents for floors) may be inconvenient and create a more complex education process for the EVS department.

Because organic materials such as blood and protein inactivate many disinfectants, organic matter must be removed from surfaces before applying the disinfectant. A large number of disinfectants registered by the EPA are acceptable for routine decontamination of the environment.[1,6,13]EPA-registered quaternary ammonium compounds (quats) are most frequently selected for cleaning environmental surfaces. Occasionally, phenolics have been used when encountering greater contamination, such as in the

operating rooms. Bleach (1:10 dilution or 1.5 cups of bleach in a gallon of water) has gained wide acceptance as an effective and inexpensive disinfectant for blood spills, gastrointestinal outbreaks (norovirus), and spore-forming organisms (*C. difficile*). The EPA also has a list of sporicidal disinfectants effective against *C. difficile*.[12]

Disinfectants and detergents must be used according to the manufacturer's instructions on the label (e.g., dilution, compatibility, contact time, storage, shelf-life). If the manufacturer's recommendations are not followed, the user assumes the liability for any problems or adverse effects; this disclaimer is stated on the labels of all EPA-registered products. Many disinfectants require a 10-minute contact time, which is not always practical and usually requires more than one application of the chemical because most water-based disinfectants dry within 2 minutes.[14]Multiple studies have shown that a 1-minute contact time is sufficient, and there is no evidence that a 10-minute application results in greater reduction of infections than a 1-minute exposure.[2,6]However, inspectors, surveyors, and other auditors will refer to product label instructions regarding wet contact time when evaluating facility compliance.

Newer 0.5 percent and 1.4 percent hydrogen peroxide solutions for surface cleaning have been found to be highly effective.[2,15]They are bactericidal and virucidal within 30 to 60 seconds, which is the fastest nonbleach contact time.[1]The contact time for mycobacteria is 5 minutes. Hydrogen peroxide falls into the lowest toxicity risk level; it is noncorrosive, compatible with most surfaces, releases a minimally offensive chemical odor, requires only one step to clean and disinfect, and can be purchased as a wipe and liquid. It is more expensive than a quat and bleach.[14]

Detergents and disinfectants that are ready for use or dispensed in premeasured amounts may be preferred over those that require mixing. Disinfectants that are ready for use are sold in individually packaged impregnated wipes, in canisters of multiple impregnated cloths, and as premixed liquids with and without sprays. To ensure their efficacy, premixed solutions should not be further diluted or altered in any way. If it is necessary to prepare a cleaning solution, the manufacturer's instructions for dilution must be closely followed. Machines that dispense premeasured amounts of chemical and water are more accurate and reliable than manual mixing of solutions. Unless otherwise specified, fresh tap water should be used to dilute the disinfectant or detergent. Containers for the cleaning agents must be labeled in accordance with regulatory requirements (e.g., chemical content, name, expiration date).

Containers with multiple disposable wipes impregnated with disinfectant can make cleaning and disinfection of small spills and surfaces easier and more convenient. These wipes combine cleaning and disinfection into a one-step process at the point of care. Wipes must maintain their wetness until the manufacturer's specified contact time is reached.

It is important to prevent extrinsic contamination of disinfectants and detergents. Dispensing equipment should be well maintained and kept in a clean area to prevent contamination. Disposable containers are generally preferred. Reusable containers should be emptied, cleaned, and dried before they are refilled. The practice of "topping off" nearly empty containers of disinfectants and detergents creates a risk for introducing unwanted microorganisms. All chemicals must be discarded when they have reached their expiration date.

Antiseptics

Antiseptics are approved by the FDA as antimicrobial agents safe for use on skin. They are not to be used for cleaning inanimate objects or environmental surfaces because of their unproven efficacy on

nonhuman surfaces. Only 70 to 90 percent isopropyl or ethyl alcohol can be safely used on both skin and environmental surfaces. However, alcohol dries too quickly to be an effective agent for cleaning large surfaces or spills and is expensive.

Special Circumstances

Special considerations must be taken when selecting a disinfectant for use in the following situations or areas:

1. Blood and body fluids

   Many disinfectants are inactivated by blood and other organic matter. If the spill is small, it can be cleaned and disinfected in one step by pouring the disinfectant directly on the spill and cleaning up after the appropriate contact time for the disinfectant has been reached.[3,6] If the spill involves a higher concentration of microorganisms, such as a large body fluid spill or a blood spill in a laboratory, absorbent material can be placed over the spill until all of the fluid is absorbed. The disinfectant solution can be poured over the spill and the absorbent material until both are thoroughly soaked with the disinfectant for the designed contact time. Then the spill site is cleaned. Absorbent powders that solidify liquids are recommended for cleaning large spills.[16]

   OSHA stipulates that blood and body fluid spills be decontaminated with one of the following: an EPA-registered disinfectant effective against Hepatitis B virus (HBV) and the human immunodeficiency virus (HIV), a tuberculocidal disinfectant, or an appropriate dilution of household bleach (5.25 to 6.15 percent sodium hypochlorite solution).[6,13] If the spill occurs on a nonporous surface, a 1:100 dilution of household bleach (one part household bleach plus 99 parts tap water or 0.25 cup of bleach in a gallon of water) is a highly effective disinfectant and is the least expensive.[6] A 1:10 dilution of household bleach (one part household bleach plus nine parts water or 1.5 cups of bleach in a gallon of water) is required for porous surfaces and large spills. Large quantities of blood may inactivate the higher concentration of bleach. Higher concentrations of bleach may also be damaging or corrosive to surfaces.

   If a diluted bleach solution is stored in an open container, the chlorine rapidly dissipates and therefore must be prepared daily. When stored in a spray or wash bottle or in a closed, brown opaque container, the bleach solution will remain stable for 30 days and will retain 50 percent of its initial value.[6] For example, a solution with 1,000 parts per million (1:50 dilution) chlorine would contain 500 parts per million (1:100 dilution) chlorine 30 days after initial mixing, if stored in a spray or wash bottle. Any container of bleach solution that has been prepared must be properly labeled with its contents, the dilution, and the expiration date.

   Blood and body fluid spills on carpets and upholstery are difficult to clean. Many EPA-registered disinfectants and 1:10 or 1:100 dilution of bleach will stain and/or damage carpets and upholstery. Depending on the type of fabric, these items can be cleaned using an extraction cleaning procedure and standard cleaning products. If the resulting stain is extensive or cannot be removed, the damaged item must be discarded and replaced.

   Fortunately, there is no record of anyone having acquired HBV, Hepatitis C virus (HCV), or HIV from environmental surfaces.[1] On the other hand, the surface of medical equipment surfaces may be a reservoir for these pathogens. Multiple outbreaks of HBV have been traced to contaminated

items, surfaces of hemodialysis machines, and the environment in clinical laboratories.[17,18,19] It is imperative that equipment surfaces be routinely cleaned and whenever spills occur.

2. *C. difficile* infections (CDI)

C. difficile has emerged as a major pathogen of healthcare-associated diarrhea and colitis. Multiple outbreaks caused by strains with high mortality rates have been reported.[20,21,22] The organism produces spores in feces. Surfaces contaminated with feces become a potential reservoir of spores, which can survive in the environment for 5 months.[23] One study found spores in 49 percent of rooms occupied by infected patients and in 29 percent of rooms of asymptomatic carriers. The majority of spores were found in the bathroom and on floors, but they were also found on electronic thermometers, blood pressure cuffs, call lights, television controls, phones, bedrails, linen, intravenous (IV) pumps, tube feedings, light controls, and window sills. Carpeted rooms were more heavily contaminated than uncarpeted ones. *C. difficile* spores were also isolated from surfaces outside of colonized and infected patient rooms, including the workstation of physicians and nurses and in rooms of uninfected patients. Studies have documented that patients acquired CDI from the contaminated hospital environment.[24]

The most frequently used disinfectants (quats and phenolics) are not sporicidal. Some of these agents create harsh conditions that prompt *C. difficile* to transform from the vegetative state to spores.[6] In the past, chlorine-containing compounds were the only sporicidal disinfectants available. Newer EPA-registered sporicidal disinfectants consisting of hydrogen peroxide compounds are also available.[12]

Although bleach is less expensive than other sporicidal agents, its routine use may be problematic. APIC and the CDC recommend a 1:10 dilution of household bleach to clean units with high endemic rates of CDI and during outbreaks of CDI.[6,23,25] Prolonged exposure of metal surfaces and equipment to bleach may lead to pitting and corrosion. Bleach also discolors nonmetal surfaces of hospital furniture. Furthermore, bleach can irritate the respiratory passages of patients, visitors, and HCP. It can cause respiratory distress and induce an asthma attack in susceptible individuals. The odor may also increase nausea in some patients.

Nonbleach-containing sporicidal agents also exude a strong odor that may be unacceptable to some individuals. At present, these newer products are usually more expensive than household bleach.

Ideally, bleach or a sporicidal agent should be used in rooms occupied by patients with CDI, especially for terminal cleaning and during an outbreak. More rigorous use of bleach or other sporicide may be necessary when routine cleaning practices are insufficient to reduce the risks of cross-contamination.[26]

Sporicidal disinfectants alone will not control CDI outbreaks. EVS personnel must follow cleaning procedure according to facility policy and adhere to Contact Precautions by wearing gloves and gowns when cleaning rooms occupied by CDI patients to protect themselves and to prevent the spread of spores.[23,24,25,27] Researchers have recently shown that use of ultraviolet C (UV-C) light and hydrogen peroxide vapors after physical cleaning will further reduce *C. difficile* from the environment, including from unused supplies.[2,14,28,29,30]

3. Diarrheal outbreaks: norovirus model

   Meticulous hand hygiene is the key to preventing transmission of microorganisms that cause gastroenteritis. However, when the environment is heavily contaminated, especially during diarrheal outbreaks, hand hygiene alone is not adequate. Extra efforts are needed to thoroughly clean the environment. Because norovirus is the leading cause of gastroenteritis and responsible for multiple outbreaks in healthcare facilities, cleaning methods to control the spread of norovirus serve as a model for controlling diarrheal outbreaks not associated with *C. difficile*.

   During outbreaks, the environment, especially high-touch surfaces, are heavily contaminated with microorganisms. High-touch surfaces include commodes, toilets, toilet handles, faucets, bathroom rails, bedrails, telephones, computers, and food preparation areas. The CDC recommends that these surfaces be cleaned and disinfected at least three times per day and that low-touch surfaces be cleaned at least twice a day.[31]Written procedures should emphasize meticulous cleaning moving from the least soiled surface to the most contaminated ones. Gowns and gloves must be worn not only for patient care but also when performing cleaning tasks.

   Despite numerous laboratory efforts, routine cell cultures and animal models have failed to satisfactorily replicate Norovirus. This is a major obstacle in the development and testing of exiting and/or new disinfecting products.[32]However, the EPA lists both quats and bleach as being effective against the virus.[13]Regardless of the disinfectant selected, it is important to follow the manufacturer's directions for use and to clean thoroughly. When isolation precautions are discontinued but the patient remains hospitalized, the patient should be moved to a clean room as available, and the previously occupied room terminally cleaned.

   Because curtains are touched frequently, CDC and AHE recommend changing privacy curtains when a patient on Contact Precautions is transferred or discharged.[7,31]In addition, upholstered furniture and carpeting must be cleaned and disposable items discarded. CDC recommends that facilities consider steam cleaning furniture and carpets if feasible.[31]If the furniture and carpet are not soiled with feces, using UV-C light or hydrogen peroxide vapors obviates the need for steam cleaning furniture and carpeting.[2,14,28,29,30]Using these novel methods after physical cleaning helps ensure an environment free of diarrheal pathogens.

4. *Mycobacterium tuberculosis*

   Mycobacteria are innately more resistant to disinfectants than most microorganisms. Therefore, it is important to clean surfaces possibly contaminated with mycobacteria, such as *M. tuberculosis,* with an EPA-registered tuberculocidal disinfectant.[1,6,13,33]Disinfectants not tested against the organism are not considered effective. Many tuberculocidal disinfectants require 5- to 10-minute contact time to be effective. Some manufacturers have managed to reduce the contact time. To ensure effective cleaning, the manufacturer's instructions for use must be followed.

5. Nurseries

   Bassinets, incubators, scales, and other equipment in nurseries must be cleaned on a routine schedule and when the patient is transferred or discharged. Infants must be removed from their beds before cleaning and disinfecting commences and not returned to them until all surfaces have completely dried.[6]To ensure the longevity of the furniture and equipment, it is important to adhere

to the cleaning instructions provided by the manufacturers of the products and to use the disinfectant recommended. Usually a quat is recommended, as some formulations containing alcohol may cloud the clear plastic on bassinets and incubators.

Because there is an association between the excessive use of a phenolic disinfectant and hyperbilirubinemia in newborns, phenolics are not recommended for use on nursery surfaces (e.g., isolettes, bassinets, scales) with which infants may have contact.[6,34] Surfaces must be thoroughly rinsed and dried after using a phenolic in nurseries.

6. Creutzfeldt-Jakob disease (CJD) and variant CJD (vCJD)

   The agents of CJD and vCJD are resistant to commonly used disinfectants. However, there is no evidence that CJD or vCJD has been acquired from environmental surfaces that are routinely cleaned.[6]

   The most likely areas where environmental surfaces might become contaminated with CJD or vCJD are in the operating rooms, autopsy areas, and clinical laboratories. Prior to use, surfaces that might become contaminated during a surgical procedure, autopsy, or specimen processing must be lined with impermeable coverings. If unprotected surfaces become contaminated with central nervous system tissues or cerebrospinal fluids containing CJD or vCJD, the body fluids must first be removed using absorbent materials. Then the surface must be flooded with 10,000 to 20,000 parts per million sodium hypochlorite solution (1:5 to 1:3 dilution, respectively, of household bleach). After exposing the surface to the chemical for 30 to 60 minutes, the solution must be removed using additional absorbent material. All materials must then be discarded into a biohazardous waste container. Finally, the surface must be rinsed thoroughly with water.[1]

7. Severe acute respiratory syndrome (SARS)

   SARS is caused by the coronavirus. Studies on the virus have shown that it can survive in feces and urine for up to 2 days. EPA-registered virucidal disinfectants and/or a 1:100 dilution of household bleach readily kill the virus.[6] Because the environment of patients with SARS is heavily contaminated, surfaces must be thoroughly cleaned daily and on discharge. Personnel performing cleaning tasks must follow isolation precautions meticulously and wear a gown, gloves, mask, and protective eyewear.[6,25]

8. Multidrug-resistant organisms

   Multidrug resistant organisms (MDROs) include MRSA, VRE, multidrug-resistant Gram-negative bacilli, extended-spectrum beta-lactamase producers, carbapenem-resistant Enterobacteriaceae (CRE), and metallo-beta-lactamase CRE. At this time, MDROs have not developed resistance to disinfectants, so no single disinfectant has been specified for use on MDROs.[6] Because these organisms are hardy, removal of MDROs from contaminated surfaces requires meticulous, rigorous cleaning. Contact Precautions must be followed for patient care and cleaning tasks.[25,35] Privacy curtains must be changed after the patient is discharged.[7]

9. Isolation rooms

Except for situations previously discussed, there are no specific disinfectants for use in isolation rooms.[6,25,35] When Isolation Precautions are discontinued but the patient remains hospitalized, the patient should be moved to a clean room as available, and the isolation room should be terminally cleaned and decontaminated using the appropriate disinfectants.

10. Rarely encountered or unusual pathogens

    When a rarely seen or unusual organism or an agent of bioterrorism is encountered, it is important to consult the local health department and/or the CDC on methods to clean the environment. According to CDC, most disinfectants are ineffective against *Cryptosporidium*. However, current cleaning and disinfection practices appear satisfactory to prevent healthcare-associated transmission. A 1:10 dilution of household beach is effective against *Escherichia coli* O157:H7.[6] If agents of bioterrorism are encountered and not genetically altered, 1:10 dilution of bleach is used for the initial cleaning, followed by UV irradiation or hydrogen peroxide vapor.[2,6]

    Genetically altered agents may require more drastic decontamination methods, such as chlorine dioxide gas. In these instances, the facility must consult public health experts at the state or federal (CDC) level.[6]

11. Bed bugs

    Bed bugs can be problematic in healthcare facilities, especially those located in major metropolitan areas. Infested patients, visitors, and HCP can bring bed bugs into healthcare facilities on their clothing, in their personal belongings (purses, computers), and in assistive devices such as wheelchairs and walkers. Indications of bed bugs include bites on the individual (some individuals do not react to the bites), egg casings, fecal stains (rusty-colored blood spots due to blood-filled fecal excretions), skin casts in cracks and crevices of belongings, a sweet musty odor, and actually finding the bug. Patients may inform their caretakers that they have bed bugs. If not detected early, the bugs may invade hospital linen, and reside in the cracks and crevices of furniture (mattresses, bed frames, chairs, tables), behind picture frames, under wallpaper, in upholstery and carpeting, and between floor tiles and moldings. Bed bugs can survive for a year without feeding.

    If bed bugs are suspected, the patient must be examined and his or her personal belongings should be placed in plastic bags that are tied securely closed or in other sealed containers. Environmental clutter should be removed and the area vacuumed, preferably using a HEPA-filtered vacuum. Reusable equipment such as walkers and wheelchairs should be thoroughly cleaned. For heavy and/or persistent infestations, insecticides may be required.[36] HCP should wear protective gowns and gloves while providing care and when decontaminating infested areas.[25]

    When notified about bed bugs, EVS may assist with containment procedures and will contact the facility exterminator. The exterminator will evaluate the furniture and room for infestation, identify items that need to be contained and discarded, apply insecticide, and/or treat the room with high heat (118°F or 48°C for 1 hour).[37] Specially trained dogs may also be used to detect infested sites.

Evaluating Disinfectants

Many types of disinfectants are registered with the EPA. Some are more effective and easier to use than others. When selecting disinfectants or cleaning products, factors to consider include ease of use,

efficacy, acceptability, safety, and cost. Resources offered by the manufacturer, such as educational materials and programs, research studies on the product, reliability of the distributor, and availability of the product are important additional considerations.

The IP should have a thorough knowledge of the cleaning agents and disinfectants used by the EVS department. In addition to product names, the IP should know the active ingredient in the product, directions for use, where and how it is used in the facility, how to contact the manufacturer with questions, and where to find the safety data sheet (SDS) (formerly known as material safety data sheet or MSDS). In many facilities, the infection prevention and control committee is required to approve the disinfectants selected for use. (See **31. Cleaning, Disinfection, and Sterilization** for details on types of disinfectants and uses.)

Standard Precautions

The term "Standard Precautions" applies to a synthesis of universal precautions and body substance isolation.[7,25,38] These practices such as wearing appropriate personal protective equipment (PPE) are designed to minimize the risk of transmission of bloodborne pathogens and pathogens from moist body substances. HCP are instructed to handle (1) blood; (2) all body fluids, secretions, and excretions, except sweat; (3) nonintact skin; and (4) mucous membranes as though they might contain infectious agents. EVS personnel must adhere to Standard Precautions when performing cleaning tasks.[7]

Personal Protective Equipment

In accordance with OSHA and CDC, EVS managers and supervisors, in conjunction with IPs and other HCP, determine when PPE is necessary, write usage guidelines, and select and purchase appropriate products. They should educate EVS personnel about PPE, make sure PPE is available, and monitor usage.[5,7,25,39] The PPE training program must include the following:

1. When PPE is worn
2. What PPE to wear
3. How to don, remove, adjust, and wear each type of PPE
4. Limitations of each type of PPE
5. Care, maintenance, useful life, and storage or disposal of PPE
6. Written certification indicating that the employee has received and understood the training

The PPE most commonly used by EVS personnel are gloves, gowns, and protective face wear (mask and eyewear). Gloves must be nonabsorbent. A variety of impervious gloves (latex, latex-free, vinyl, nitrile, rubber) are available. In most situations, disposable gloves are preferred because cleaning, decontaminating, and storing reusable gloves is cumbersome. Heavy-duty gloves are recommended if the task (e.g., handling waste) has a high risk for percutaneous injury. Most heavy-duty gloves are reusable but must be decontaminated after use and stored appropriately. When there is a potential for splashing or splattering, a fluid-resistant or fluidproof gown, apron, mask, and protective eyewear are required.

Disposable apparel must be discarded into the appropriate waste containers after use. Protective apparel that is visibly soiled with blood and other potentially infectious materials must be placed in a biohazardous waste container. Reusable items, especially those that have been contaminated, must be disinfected at the end of each shift or sooner depending on environmental and patient care circumstances. There must be a designated place for soiled reusable aprons, gloves, and other

reusable PPE until they can be disinfected. Reusable PPE should not be stored in personnel lockers or removed from the facility.

When cleaning the room of a patient on Isolation Precautions, personnel are required to wear protective apparel, even if the patient is out of the room or has been discharged. For example, when cleaning the room of a patient with suspected or confirmed tuberculosis (TB), EVS personnel must wear a N95 respirator.[25,33] EVS personnel must not remove the PPE until he/she leaves that room. Additionally, the doors to the anteroom (if present) and to the patient room must be kept closed during cleaning.

Cleaning Methods

Policies and Procedures

Every healthcare facility must have written policies and procedures for cleaning. Policies and procedures should be specific to the facility yet meet regulatory requirements and guidelines established by government agencies, accrediting bodies, and professional organizations. Policies and procedures should address departmental concerns, specify cleaning procedures, list the necessary cleaning agents and equipment, provide cleaning schedules, and may include quality control methods. The IP should collaborate with EVS to develop these policies and procedures. At the same time, because these policies and procedures affect the entire facility, a multidisciplinary group consisting of nursing, administration, facilities, pharmacy, clinical engineering, materials management, pharmacy, food services, and information systems should be consulted. AHE's *Practice Guidance for Healthcare Environmental Cleaning* outlines cleaning procedures for a variety of departments in the healthcare facility.[7]

The cleaning process minimizes cross-contamination. Cleaning procedures begin with the least soiled areas and move to the most soiled areas. Cleaning also proceeds from high to low surfaces, allowing dust and debris from high surfaces to fall to lower ones before the lower surfaces are cleaned. To ensure that all surfaces are reached, cleaning should be performed in a systematic manner. After selecting a starting point, such as the door or window, work typically progresses from that point in either a clockwise or counterclockwise direction.

Dusting

Dust contains fungal spores. To capture dust without aerosolizing spores, dusting should be performed using a cloth or dust mop that is chemically treated or made of microfiber. Dusters should never be shaken. All surfaces and fixtures above shoulder height—such as the tops of doors, wall-mounted televisions, overhead lights, pictures, high shelves, and ledges—should be dusted with a specially designed mop or a "high duster," that reaches high surfaces. Dusting should be performed first so particles and dirt that fall to the floor will be captured when the floor is cleaned.

During the dusting procedure, ceilings, ceiling tiles, and walls should be visually inspected for peeling areas and stains, which indicate holes in the roofs and/or leaks from pipes above dropped ceilings or behind walls. Moist false ceiling tiles and drywall provide a growth media for fungi. Leaks and holes should be repaired promptly depending on the extent of the damage and the risks to the environment. Stained tiles should be replaced quickly. Although EVS personnel do not generally repair or replace these items, they are responsible for reporting the problems they encounter to their supervisor or the designated facilities repair person.

Walls, Windows, and Doors

Walls, windows, and doors should be spot-cleaned as needed and completely cleaned on a regular schedule. Door handles and light switches are considered high-touch items. They should be cleaned at least daily, more frequently if an outbreak is occurring, and when a patient is discharged or transferred.[1,7,31] Although designed for floors, microfiber mops can serve as an excellent tool for cleaning walls. However, a clean mop head must be used in these instances.

Horizontal Surfaces

High-touch horizontal surfaces should be wiped at least daily and when visibly soiled with a clean cloth impregnated with an EPA-registered disinfectant. Items that fall in the high-touch category vary by department or area (see Table 107-1). The cleaning cloth can consist of cotton or microfiber, or it can be a disposable synthetic material.

Table 107-1 Examples of High-touch Surfaces

Patient Room	Bathroom	Operating Room	Kitchen	Office
Bed controls	Bedpan cleaners/flushers	Anesthesia equipment and controls	Cabinet handles	Chair for desk
Bed rails	Call light	Anesthesia supply cart	Countertops	Computer keyboard
Bedside table	Doorknobs	Arm boards	Dishwasher handles and controls	Desk
Bedside commode	Faucet handles	Autoclave door handles	Doorknob	Light switch
Blood pressure cuff	Hand rails	Back table	Drawer handles	Phone
Cabinet knobs	Handheld shower handles	Computer keyboard	Faucets handles	
Call light	Light switch	Door handles	Light switches	
Chair arms/seats	Sinks	IV poles	Phones	
Computer keyboard	Toilet flush	Light switches	Refrigerator handles	
Doorknobs	Toilet seat	Mayo stand	Stove tops and controls	
Glucometer		Medication cart		
Handheld bar- coding devices		Operating bed		
Handheld television control		Operating bed controls		
IV poles		Operating bed straps		
Light switches		Overhead surgical lights		
Monitoring equipment		Patient monitors		
Overbed table		Ring stand		
Privacy curtains		Sponge counter		
Telephone		Storage cabinet door handles		
Thermometer		Telephone		
Ventilator controls		Warmer door handles		

During diarrheal outbreaks in patient areas, the frequency of cleaning for high-touch sites should be increased to at least three times a day, and less frequently touched items should be disinfected at least

two times per day.[31]

Mattresses and Pillows

Mattress and pillow covers are made of moisture-resistant material and are easy to clean. Fabric covers are not recommended. If used, they must be laundered between patients. Mattresses and pillows with cracks, tears, and permanent stains must be immediately discarded. Mattresses and pillows must be cleaned and disinfected with an EPA-registered disinfectant and according to manufacturer's recommendations between each patient and when visibly soiled.

Many healthcare facilities have contracts with vendors for specialty mattresses and bed frames. The contracts usually stipulate that the vendor deliver, assemble, remove, and decontaminate these mattresses and beds. IPs are responsible for reviewing the company's procedures for cleaning and disinfecting these bed systems. The institution should develop a protocol to ensure that HCP decontaminate the surfaces of these bed systems before they are removed from a patient's room. Bed systems should be placed in a designated area for pickup by the vendor and not left in the hall. If a facility decides to clean and disinfect the specialty bed system, the manufacturer's directions must be closely followed. Because many specialty mattresses and frames are complicated to decontaminate, personnel assigned this task must be appropriately trained and any specific cleaning/disinfecting products or supplies must be available on-site.

Privacy Curtains

The use of privacy curtains varies by patient, and these curtains are often a high-touch item. When patients are not on Isolation Precautions, privacy curtains should be changed and cleaned on a routine schedule and when visibly soiled. The CDC does not suggest more frequent changes if the patient is on Isolation Precautions, but AHE does.[7'35]If the patient is on Contact Precautions, especially for *C. difficile*, MDROs, or norovirus, AHE recommends that the curtains be changed after the patient is discharged, transferred, or taken out of isolation.[7]If the facility follows these recommendations, it must have an adequate supply of curtains and personnel to remove and hang curtains.

The design of some newer curtains makes hanging and removal easier. In one design, the bottom two thirds of the curtain snaps off while the top third of the curtain remains attached to the curtain track, eliminating the need for tall ladders. The ease of changing these curtains may override their higher cost.

Multiple studies have shown that privacy curtains easily become contaminated with microorganisms and are a source of cross-transmission of pathogens.[40,41,42]Newer-designed curtains have been impregnated with an antimicrobial coating consisting of one of the following: silver-based compounds, silane quats, triclosan, or zinc pyrithione.[43]When evaluating antimicrobial curtains, the facility should verify that the textile has an EPA registration. This indicates that the manufacturer has shown that the impregnated textile decreases microbial growth, reduces degradation of the fabric over time, and controls odors.[44]The long-term impact of using antimicrobial-impregnated privacy curtains, especially regarding a possible impact on MDROs, is unknown.[45]

If an institution has laundry facilities to wash and dry privacy curtains, the area must meet regulatory requirements for a laundry service. The proper washing and drying temperatures must be reached and the appropriate chemicals must be used. Because these requirements are difficult to achieve and

monitor, AHE recommends that healthcare facilities consider using contracted linen and laundry services that meet regulations and are accredited by the Healthcare Laundry Accreditation Council.[7](Also refer to **111. Healthcare Textile Services**.)

Window Treatments

Window treatments usually consist of curtains, shades, and blinds. Window curtains are not as frequently touched as bedside curtains and do not need to be changed as often. These curtains should be washable or cleanable. All curtains, shades, and blinds should be cleaned on a regular schedule and when contaminated. Shades are easier to clean than blinds. Cleaning individual slats in blinds is tedious and time-consuming.

Bathrooms

Bathrooms must be cleaned and disinfected at least daily and when visibly soiled. During *C. difficile* and other diarrheal outbreaks, the frequency should be at least three times per day.[31]The toilet seat and flusher handle, faucet handles, handrails, soap dispenser, nurse call cord, bedpan dispenser, light switch, and doorknobs are high-touch surfaces that require special attention.

The ceramic tile grout around the commode and tub or shower should be checked for mold. If present, the mold must be removed. Countertops that are cracked or moldy must be replaced. If present, mold must be removed using friction and diluted bleach or an appropriate, commercially prepared product.

When a patient has a bedside commode, EVS personnel must clean and disinfect it at least daily and when visibly soiled unless facility policy assigns responsibility for this task to nursing personnel. When no longer needed, the basin must be emptied and the surfaces of the commode decontaminated before it is moved out of the patient's room. This step is particularly important to prevent the spread of enteric pathogens such as norovirus and *C. difficile*.

Hand Hygiene Agents

In many healthcare facilities, EVS assists in the selection of hand hygiene products and is responsible for maintaining these agents. Because there are multiple product options, EVS personnel should be knowledgeable about the different types of solutions, where each product is used, and how to fill and replace dispensers. EVS personnel should also routinely check expiration dates.

As with disinfectants, the selection of hand hygiene agents is based on use, efficacy, cost, and acceptability by staff. Selection of hand hygiene product should be conducted by a multidisciplinary committee consisting of nurses, physicians, the EVS manager, purchasing agent, and administrator and infection prevention and control department. Hand hygiene products include plain soap (contains no antimicrobial properties), antiseptic (antimicrobial) agents, or alcohol-based waterless agents. Plain soaps are typically placed at sinks for routine hand hygiene in areas where there is minimal potential exposure to blood and body fluids. Examples include public restrooms, administrative departments, offices, and other nonpatient care areas. Antiseptic soaps are recommended in areas where hands have a high risk of acquiring and transmitting HAIs (e.g., patient care areas, laboratories, and decontamination and sterilization).[4]

Soaps are available as a bar, liquid, and tissue or leaflet preparations. Measures must be taken to prevent them from becoming contaminated. Bar soaps are small and should be placed in well-drained containers to minimize contamination. Because maintaining clean dry containers for bar soaps is

cumbersome, liquid soaps are often preferred. It is also easier to use disposable pre-packaged containers of liquid soaps, which are discarded when emptied. Emptied reusable containers must be cleaned and dried before they are refilled. The practice of "topping off" often leads to contamination.[4]

Most antiseptics contain one of the following antimicrobial agents: chlorhexidine, triclosan, chloroxylenol (PCMX), iodophor, quat, or alcohol. The antimicrobial activity and degree of persistence of the products vary. Those containing chlorhexidine, triclosan, PCMX, and alcohol are the most popular agents. Chlorhexidine has the broadest spectrum, greatest efficacy, and most sustaining effect.[4]Although recent studies have shown the toxic effects of triclosan, the FDA has not restricted it use.[46]PCMX is more effective against Gram-positive bacteria than Gram-negative bacteria.[4]Iodophors are highly effective against both Gram-negative and Gram-positive bacteria but tend to stain; they are primarily used in the operating rooms or other procedure areas. Antiseptic hand cleaners should be readily available in patient care areas and in areas with routine exposure to blood and body fluids.[4]

When both soaps and antimicrobial agents are used in a facility, competency of personnel on their correct use is crucial. Poor hand hygiene practice has been shown to be a leading cause of HAIs and a significant contributing factor to outbreaks.[4]

Researchers have shown that alcohol-based hand rubs (ABHR) are highly effective hand hygiene agents. The CDC strongly recommends using ABHR except when hands are visibly soiled, before eating, and after using the restroom.[4,47]Initially, the CDC did not recommend that ABHR be used after exposure to spores such as those formed by *C. difficile* or *Bacillus anthracis*.[4]It was initially thought that soap and water provided more opportunities for physically removing spores. However, current guidance recommends that ABHR be used if soap and water is not readily available, followed by using soap and water as soon as possible.[47]

Regulatory agencies have established strict guidelines on placement of ABHR in corridors to prevent fires.[48]The regulations for both gel and foam ABHR are identical:

- The corridor must be at least 6 feet wide.
- Dispensers must be at least 4 feet apart.
- Dispenser may not be installed less than 6 inches adjacent to an electrical outlet or switch (measured from the center of the container to the electrical source).
- If mounted over carpeting, the area must have sprinklers and smoke alarms.

Wall-mounted ABHR dispensers may drip, staining walls, floors, and carpets. Stains, especially on carpets, are extremely difficult to remove. Therefore, mounting ABHR dispensers over carpeting is not recommended.

Before they are purchased, dispensers for hand hygiene agents should be closely evaluated for ease of use and delivery of product. Discarding disposable fillers for the dispensers is easier than reprocessing reusable ones. After mounting, the dispensers should be checked regularly to ensure that they are adequately filled, functioning properly, and dispensing the appropriate amount of solution. They should also be cleaned routinely and when visibly soiled.

Some institutions measure hand hygiene compliance based on the amount of hand hygiene products used. If done manually, EVS must save and perhaps count the number of emptied dispensers by the type of agent. Compliance rates are then calculated manually or using a computer program. Newer dispensers automatically count the number of times the agent is dispensed, eliminating the need to save and count the empty containers. These systems are time savers but are expensive and not accurate if a user presses the dispenser more than once.

Waste

Waste is collected from all areas at least daily. If large volumes of waste are generated, more frequent pickups must be scheduled. Filled waste containers must be emptied or replaced before they overflow. Each container should be lined to minimize contamination. In most areas, liners are plastic bags. Lining the container with several layers of bags is optional and helps to reduce contamination of the container if liquids spill. The inside and outside of the receptacles and their covers should be routinely cleaned and disinfected. In patient care areas and departments handling high volumes of blood and body fluids, this should occur at least daily.

There are separate containers for biohazardous and nonbiohazardous waste. Local regulatory agencies may require that biohazardous containers not in continual use (i.e., those in a procedure room or soiled utility room) be kept covered.[49](Refer to **113. Waste Management**.)

Floors and Carpets

Floors and carpets should be cleaned last to collect any debris that has dropped. Controversy exists about whether a detergent or an EPA-registered disinfectant should be used to clean hard floors. Each healthcare facility needs to decide which to use. A disinfectant must be used to clean floors in critical areas, such as isolation rooms, operating rooms, clean rooms, and other areas designated by the facility. Detergents do not eliminate as much bacteria as disinfectants; however, the microbial load quickly returns to precleaning levels after a disinfectant is used.[6]Studies have not shown floors cleaned with either a detergent or a disinfectant to be associated with an increase in HAIs.[6]

Most floors consist of terrazzo, wood, linoleum, solid or sheet vinyl, vinyl composition tile, rubber, or polylefin.[50]The type of floor determines the cleaning products and cleaning procedures. EVS personnel must be trained to follow the manufacturer's recommendations on the proper cleaning methods and agents to use. Inappropriate cleaning techniques and chemicals may damage the floor.

Floors containing rubber have gained increasing popularity in hospitals. Their cushioning effect reduces serious injuries when a person falls and provides more comfort for HCP when walking and standing. Rubber floors with a finish are easier to maintain than unfinished ones.[50]Finished floors can be cleaned using an autoscrubber. Unfinished rubber floors show more scuff marks, which are difficult to remove and require more manual cleaning time.

Traditionally, the mop-and-bucket technique has been used to clean floors. The cotton string mop and solution in the bucket become increasingly contaminated with use, significantly more so if the solution contains a detergent rather than a disinfectant.[6]The mop and solution must be changed frequently (e.g., every third patient room or hourly) and after being used to clean spills of blood, other potentially infectious materials, an isolation room, or an operating room. These mops must be laundered (by the facility or contracted service) in a manner required by regulatory agencies or discarded.

Use of microfiber mop/pad may be preferred for cleaning floors. They are constructed of densely woven polyester and polyamide (nylon) fibers that have a positive charge, thus they attract negatively charged dust, and are more absorbent than cotton mops.[6,7] Prior to use, the microfiber pads are soaked in a cleaning solution. When cotton and microfiber mops are impregnated with detergent, the microfiber mop significantly reduced the microbial load on the floor compared to the cotton mop. This was not true when both were soaked with a disinfectant.[6,7]

Cotton string mops weigh about 10 pounds, whereas microfiber mops weigh about 2 pounds, making them easier to use. Containers of disinfectants can be attached to some microfiber mop handles and poles, enabling the dispensing of solution during use. These attachments add weight and can be cumbersome for smaller individuals.

After each use, microfiber pads are changed and laundered (or discarded if proper laundering is not an option), thereby minimizing cross-transmission of microorganisms. Prior to first use and after each use, the pads are laundered at less than 140°F (<60°C).[51] The pads are then air dried or machine dried at 100 to 120°F (37.8°–48.9°C). Care is taken not to overdry them, because this results in damage, shrinkage, and shortened life. If used immediately, they may be used damp. The pads should be laundered and dried only with other microfiber products, because they attract lint from other textiles. Bleach and fabric softener are contraindicated in the wash cycle. Fabric softener is also not recommended in the drying cycle.[51] Clean dried pads are stored in clean cabinets or containers.

Microfiber pads have limitations. They may be too large to effectively clean small spaces (behind toilets) or grooved surfaces (grout between tiles), and rough cement surfaces. Nor are they effective on greasy floors in kitchens or high-gloss surfaces such as marble. The pads should not be used to strip and wax floors.

AORN recommends that the operating room floors be wet vacuumed with an EPA-registered disinfectant after all cases have been completed.[7]

Autoscrubbers can be very effective for cleaning floors, leaving them with a clean sheen.[50] These machines apply water and cleaning solution, scrub, extract the liquid, and leave the floor dry in less time than mopping. Scrubbing machines, however, are difficult to use in small spaces. They also need to be properly cleaned and maintained.

Floors also routinely undergo deep scrubbing. During this process, wax and stubborn spots are scrubbed off, then wax is reapplied. This process is lengthy and the floor is often flooded, creating a safety hazard. Therefore, deep scrubbing should be prescheduled during times of low traffic or the area should be closed to traffic when possible.

Carpets collect dust and debris and are more difficult to maintain than floors. Because the dust in carpets contains fungal spores that may induce asthma attacks and cause fatal infections in immunocompromised patients, carpets are not recommended in intensive care units, procedure rooms, high-traffic areas, laboratories, areas where spills frequently occur, and hallways and rooms housing immunosuppressed patients.

Carpets should be maintained with routine vacuuming and deep cleaning, using methods that minimize aerosolization of dust. Vacuums with HEPA filters should be used in critical areas. After a deep scrub, carpets should be thoroughly dried within 72 hours to reduce growth of fungi.[4] During deep scrubbing

and drying, carpeted areas should not be used. Carpeting exposed to repeated flooding is likely to contain fungal spores and should be replaced, preferably with nonabsorbent flooring.

Cleaning of floors and carpets should start at the back of the room and move toward the door. Furniture, equipment, and other items should be moved as necessary to enable mopping and vacuuming of areas under them. Floors should be mopped using the "S" stroke, catching dirt and debris on the leading edge of the mop. EVS personnel should pay attention to corners, edges, scuff marks, gum, tar, and other adherent substances. If the area is occupied, EVS personnel should create a dry path (half of the hall or room) to allow people to walk through without falling on the wet floor. Carpets should be vacuumed by moving the machine forward and backward, making a series of "Ns." Each stroke should slightly overlap the previous one. Stains should be removed as soon as possible.

Linen

Clean and soiled linen are stored and handled separately in accordance with state and local health department regulations. Clean linen must be stored in covered carts or enclosed cabinets and kept covered during transport. Personnel must wash their hands before handling clean linen and must wear clean attire.

Personnel must follow Standard Precautions and wear gloves and other PPE (gowns, mask, protective face and eyewear) when handling soiled linen. Linen contaminated with blood and other potentially infectious materials should be labeled or color-coded.[3,25]

Health regulations require that soiled linen be placed in covered containers or bags. Linen containers or bags must be closed securely before being placed into a chute or transported to a temporary holding cart or room. Soiled linen in chutes, carts, or holding rooms should be transported to the laundry facility on a regular schedule (e.g., daily). There is no differentiation in handling linen from isolation and nonisolation patient rooms.

Soiled linen carts should be cleaned and disinfected regularly. If available, a cart washer makes this task easier.

If laundry chutes are available, the chute room and the chute itself should be cleaned on a routine schedule and whenever spills occur. Most likely, the chute room will require daily cleaning. Ideally, laundry chutes should be designed to be at negative pressure to prevent airborne spread of pathogens in the event a bag breaks or opens.[8]

Laundry facilities must adhere to local and state regulations for such entities. There are strict requirements regarding water and drying temperatures, cleaning agents, and work flows. In addition, the Healthcare Laundry Accreditation Council offers voluntary accreditation for commercial laundry facilities. If an institution provides in-house laundry services, IPs are expected to assist in monitoring procedures and compliance with regulatory requirements. If the hospital has a contracted laundry service, the IP should tour the laundry facility, evaluate its compliance with infection prevention and control practices, observe its adherence with regulatory requirements, and become familiar with the contract responsibilities that address infection prevention and control issues. (Also refer to **111. Healthcare Textile Services**.)

Medical Equipment

If medical equipment is not adequately decontaminated, it may be a source of infection. Some equipment (e.g., IV poles, cardiac monitors, computers, and keyboards) may be easily cleaned by

wiping with a disinfectant cloth. Larger more complex equipment requires a two-step process. The surfaces of these items (such as x-ray machines, ventilators, specialty beds) must be carefully disinfected immediately after use and before they are moved out of the room. The equipment should then be taken to a decontamination area, where the necessary internal parts of the machine are removed and disinfected. For example, the outside of the ventilator is wiped with a disinfectant inside the patient's room after use and then taken to the respiratory therapy decontamination room, where the inside components are disinfected. The two-step process is also necessary for any equipment used in high-risk areas such as operating rooms, procedure rooms, and isolation rooms. It is important that each healthcare facility considers cleaning of medical equipment to be a team effort. Facilities need to clearly delineate responsibilities for cleaning medical equipment to specific personnel to avoid lapses in cleaning practice and procedure and to ensure equipment is cleaned by properly trained personnel. Adherence with proper techniques should be monitored as part of a quality/patient safety program. If cleaning is not done correctly, the integrity and warranty of expensive equipment may be compromised.

Equipment Used for Cleaning

Equipment used by EVS (cloths, mops, carts, chemical dispensers, vacuums, autoscrubbers, deep scrubbers, extractors) must be cleaned per facility policy and according to the manufacturer's instructions. More frequent cleaning may be necessary depending on the degree of contamination. Equipment should undergo routine maintenance as specified by the manufacturer and be kept in good repair by a qualified person. Maintenance and repair of mechanical equipment should be documented. Broken equipment that cannot be repaired but is still needed must be replaced.

If a facility has automatic chemical dispensers, the dispensers should be checked and calibrated routinely to ensure accuracy and to control cost. The dispensers should also receive routine maintenance in accordance with the manufacturer's recommendations.

Cleaning items, (e.g., detergent and/or disinfectant solutions, water buckets, cleaning cloths, dusters, toilet brushes, and mops) must be changed routinely and after they are used to clean blood spills or highly contaminated areas such as isolation rooms or operating rooms.[1,8,25] Using contaminated cloths and mops will result in cross-contamination of surfaces, equipment, and hands. CDC recommends changing floor mopping solutions every three rooms and at least every 60 minutes.[6] Used mops and cleaning cloths should never be returned to containers of cleaning solution. They should be laundered or discarded after use. Handles and poles for mops, dusters, and other items should also be wiped with a disinfectant after use.

Reusable cotton cloths and mops should be washed with a detergent and dried at 176°F (80°C) for 2 hours. Reusable clothes may also be disinfected by immersing in hypochlorite (4,000 ppm) for 2 minutes. Cloths and mops exposed to petroleum-based products should be discarded because they are potentially flammable.

EVS staff often use portable carts to transport supplies. Clean items (toilet paper, paper towels, and hand hygiene agents) should be stored above cleaning chemicals. Soiled dusters or mops should be placed in an impervious plastic bag and stored away from clean items; often the bag is hung on the side of the cart for transport. Mop handles/poles and "wet floor" signs should be wiped with a disinfectant before placing them on the cart. Carts must be cleaned and disinfected per facility policy and whenever visibly soiled. A cart washer may be used if available. Personal items such as purses, lunches, and drinks must not be stored on the carts.

Facilities should keep a log for cleaning equipment (such as vacuum cleaners, floor scrubbers, and carts) to track their location, to ensure that each item receives routine maintenance as recommended by the manufacturer, and to record equipment that is out of service for repairs. It is imperative that cleaning equipment is readily available and functioning properly. Bar coding is helpful in tracking equipment, especially in large institutions.

Innovative Cleaning Methodologies

In the past, the CDC did not recommend using environmental fogging with a quat, phenolic, or formaldehyde as a method of decontaminating air and surfaces.[52] In addition to being a time-consuming and costly procedure, using these chemicals for fogging was not efficacious and possibly toxic. In 2010 the CDC issued a clarification that the previous fogging recommendations do not include newer room decontamination technology (e.g., ozone mists, vaporized hydrogen peroxide). However, CDC does not yet make any recommendation regarding these newer technologies.

Recent studies have shown that ultraviolet (UV) irradiation and hydrogen peroxide vapor are effective in disinfecting the air and surface environments. Because the presence of organic material reduces efficacy, the room must be cleaned prior to using either method.[2,28,29,30] In addition, the room must be completely unoccupied during these procedures. These methodologies do not replace daily cleaning and, due to their cost, are often used for terminal cleaning or in outbreak situations.

UV light destroys the DNA of microorganisms. It kills vegetative bacteria in 5 to 25 minutes and *C. difficile* spores in 50 minutes.[2,14] Investigators found that UV treatment further reduced the microbial load of MRSA, VRE, and *C. difficile* spores significantly, even after the rooms were cleaned.[2,14,28] During UV irradiation, furniture and equipment must be moved away from the walls to allow the rays to reflect off all surfaces. When the walls are painted with nanoscale metal oxides to increase reflection, the effectiveness of UV irradiation is significantly enhanced. The heating, ventilation, and air-conditioning (HVAC) system does not need to be turned off during irradiation.

Similarly, treating a cleaned room with vaporized or aerosolized dry mist hydrogen peroxide significantly reduces HAIs, especially *C. difficile* and many infections caused by MDROs.[2,14,29] The process evenly distributes hydrogen peroxide throughout the room. This method is useful for cleaning complex equipment and furniture and does not require moving them away from walls. Supplies left in the rooms are also decontaminated and do not need to be discarded.[30]

Hydrogen peroxide vapors can be harmful if inhaled. Prior to decontamination, the room must be unoccupied, the HVAC system switched off, and doors taped. Decontamination takes approximately 2 to 5 hours.[2,14]

The costs of the UV and hydrogen peroxide vapor systems are significant. When evaluating the systems, facilities must weigh expense with the potential cost savings associated with lowering HAI rates.

Cleaning Schedules

Facilities should develop written cleaning schedules to meet the needs of each area being serviced. Cleaning schedules should specify the frequency and timing for cleaning each area of the facility and

should be closely followed by EVS staff. Below are recommended cleaning procedures and schedules for specific areas.[1,7,8]

Inpatient Rooms

Cleaning to be performed and when the patient is discharged includes:

- High dusting;
- Spot cleaning of walls, windows, and doors;
- Cleaning of light fixtures, ledges, tables, chairs, beds, and floors;
- Vacuuming of carpets should be performed daily and when the patient is discharged.

Close attention should be paid to cleaning frequently handled medical equipment (e.g., sphygmomanometer, cardiac monitor, IV pump, IV pole, computers).

The same daily cleaning procedures should be followed for isolation and nonisolation rooms. After use in an isolation room, cleaning equipment (water and bucket, cleaning cloths, mop head) should be discarded or disinfected before use in another room. Only clean equipment should be used in rooms of patients who are immunocompromised (such as those who are neutropenic and those who are new transplant recipients).

Operating Rooms

Cleaning operating rooms requires a team approach involving EVS, nursing, and anesthesia personnel.[7,8] Personnel must follow specific cleaning principles in the operating rooms. The operating room suite should have dedicated cleaning tools (e.g., carts, buckets, mop handles, dusting poles, vacuums, floor machines).[7,8] To prevent aerosolization of chemicals, EVS staff should wipe surfaces with disinfectant-saturated wipes or microfiber cloths instead of using spray bottles of disinfectants. Because blood and body fluid spills are common in the OR, EVS staff should use disinfectants that are EPA-registered as effective against HBV and HIV. Sodium hypochlorite is not recommended for routine use because it can cause pitting of metal and some other surfaces.[6] Alcohol is not recommended for damp dusting large environmental surfaces because it dries too quickly. Reusable cleaning cloths must be freshly laundered and lint-free.

There are three distinct cleaning times for operating rooms: before the first case of the day, between cases, and at the end of the day.[7,8] Before the first case of the day, horizontal surfaces in the operating room should be damp-dusted with a clean lint-free cloth or a wipe dampened with a disinfectant. This task may be performed by nursing personnel. They also clean minor blood and body fluid spills and splatters during a case.

After each case, EVS, nursing, and anesthesia personnel decontaminate horizontal surfaces, equipment, examination tables, anesthesia machines, medication carts, and other items used during a procedure. Personnel should pay particular attention to high-touch surfaces, taking care not to overlook machine controls, the tops of linen hampers, waste containers, computers, and phones. Cleaning of equipment should be delegated to personnel specifically trained to perform each task. Clean, lint-free cloths or disposable wipes should be used for each case. Cleaning cloths or wipes should be changed frequently and after contact with blood and body fluids. The cleaning process should progress from high to low

and from clean to dirty. Items that are reprocessed, sharps, and biohazardous and nonbiohazardous waste must be placed in their respective containers and transported to their respective holding areas.

Floors in the operating rooms must be cleaned and disinfected after each case. Reusable string or microfiber mops may be used in between cases and should be changed after each use.[7] If a cotton mop-and-bucket system is used, a clean mop head and fresh disinfectant solution must be used for each case. It is only necessary to clean a 3- to 4-foot perimeter around the operative table after each case unless wider perimeter of contamination is identified.[8] Placing tacky mats on the floor at the entrances to operating rooms is not recommended. There is no evidence that they help prevent infections.[8]

At the conclusion of the operating schedule, blood spills and splatters not wiped up during the case must be cleaned and all items in the operating room decontaminated. Personnel should pay meticulous attention to high-touch surfaces. AORN recommends that floors be cleaned with a wet-vacuum and an EPA-registered disinfectant after the completion of scheduled cases.[8] Ventilation grilles, shelves, and cabinets in the operating rooms should be cleaned routinely and when soiled. If not removed, dust and particles collecting in these areas can become airborne and be a source of contamination or infection. Scrub sinks, work rooms, utility rooms, and corridors should also be thoroughly cleaned and disinfected regularly when OR traffic is low, not in use, and/or whenever visibly contaminated.

Procedure Rooms

Procedure rooms are cleaned and disinfected in a similar manner to operating rooms. After each case, all horizontal surfaces and shields should be cleaned and disinfected.[6,7] Floors may be spot cleaned unless more extensive decontamination is necessary. At the end of each day, all surfaces and the floor should be thoroughly cleaned and disinfected. Walls should be cleaned on a routine schedule and as needed.

Examination Rooms

After each patient, linen or paper on the examination table must be changed or discarded, respectively.[7] Reusable pillows, patient care equipment such as blood pressure cuffs, and horizontal surfaces must be wiped with a disinfectant. Walls and floors should be spot cleaned as needed.

At the end of each day, all horizontal surfaces and the entire floor must be thoroughly cleaned and disinfected. Used suction containers, if present, must be changed, and all waste containers must be emptied or, if disposable and almost full, must be discarded.

Dialysis Unit

Outbreaks of viral hepatitis that have occurred in dialysis units have been linked with contaminated environmental surfaces (dialysis chair or bed, countertops, external surfaces of dialysis machines, scissors, hemostats, clamps, blood pressure cuffs, stethoscopes). Therefore, these surfaces must be routinely disinfected with an EPA-registered disinfectant after each patient. Blood splatters and spills must be cleaned and disinfected immediately using a disinfectant effective against *Mycobacterium tuberculosis* or HBV and HIV or a 1:100 dilution of household bleach.[6] The dialysis machines must be disinfected according to the manufacturer's specifications. Waste containers should be lined with plastic bags; bags must be closed securely and removed after each patient. The waste containers should be

disinfected at the end of each day. Floors should be cleaned and disinfected at the end of each day and when visibly soiled. (Refer to **39. Dialysis**.)

Dental Examination Areas

The CDC classifies environmental surfaces in dental offices as clinical contact and environmental surfaces.[6] Clinical contact surfaces are equivalent to high-touch surfaces. Uncovered high-touch surfaces in examination areas (instrument tables, instrument handles, switches, exam lights, sink handles, computer keyboards, x-ray machine controls) must be disinfected with an EPA-registered disinfectant after each patient. The disinfectant must be either tuberculocidal and/or effective against HBV and HIV.

Disposable coverings on clinical contact surfaces such as lights and handles must be removed and discarded after each patient. These surfaces must be disinfected if the disposable coverings are torn or damaged, when the surface is visibly soiled, and at the end of the day.

In contrast to clinical contact surfaces, environmental surfaces (sinks, countertops, waste containers) must be cleaned and disinfected at least daily and whenever visibly soiled.[6] When the environment is contaminated with blood or body substances, it must be cleaned and disinfected immediately.

Clinical Laboratories

Laboratories require daily cleaning. Countertops must be decontaminated after each shift and whenever spills occur. Most likely, laboratory personnel perform this task. When the laboratory closes, EVS performs a more thorough cleaning of countertops and sinks. EVS personnel do not clean laboratory instruments or equipment. Cleaning schedules for laboratories open 24 hours a day require coordination between EVS and laboratory personnel.

Both biohazardous and nonbiohazardous wastes must be collected at least daily. Laboratories operating 24 hours a day require more frequent waste removal, perhaps at least once a shift. Floors must be cleaned and disinfected daily.

Offices and Conference Rooms

In offices and conference rooms, weekly dusting of horizontal surfaces and cleaning of floors or vacuuming carpets is sufficient, unless they are visibly soiled. Noncritical surfaces, including high-touch surfaces, may be cleaned with a detergent instead of a cleaner/disinfectant.[6,7]

Clean Rooms

In a healthcare facility, a clean room is designed to control airborne contaminants to within predetermined limits. Healthcare providers most frequently use clean rooms for the compounding of sterile pharmaceutical products. A clean room consists of an anteroom and an inner work room with HEPA air filters and closely controlled temperature and humidity levels.

Similar to the operating room, clean rooms have dedicated cleaning equipment. Cleaning equipment must be cleaned and disinfected per an established schedule. Cleaning starts from the innermost work room (location of laminar airflow hood) and moves outward to the anteroom.

Depending on the class of the clean room and local regulatory requirements, the cleaning of surfaces and floors may need to be performed more than once a day and may require documentation in a logbook.[7] Cleaning effectiveness must be performed, evaluated, and documented per facility policy.

Ambulatory Surgery Centers

The number of ambulatory surgery centers (ASCs) in the United States has grown significantly in the last decade, but only recently have regulatory requirements addressing infection control been rigorously enforced. The operating rooms and patient care areas in an ASC must be cleaned and disinfected in the same manner as operating rooms in acute care facilities. However, a survey of 68 ASCs showed that 18.8 percent had environmental cleaning issues. It was found that 12.7 percent of high-touch surfaces in the operating rooms were not appropriately cleaned with an EPA-registered disinfectant, and 18 percent of high-touch surfaces in patient care areas outside of the operating room were not properly cleaned with an approved disinfectant. Blood glucose meters were not cleaned and disinfected after each use in 32.1 percent of the surveyed facilities.[53]

After a serious outbreak occurred in 2009 in Nevada, the U.S. Department of Health and Human Services and The Joint Commission (TJC) initiated more rigorous and focused infection control surveys using criteria consistent with acute care.[54]A 2013 report by TJC stated that two of the top five most challenging standards for ASCs to meet during the first half of 2013 were preventing HAIs associated with medical equipment, devices, and supplies and assessing the risk for acquiring and transmitting infections.[55]Many ASCs need qualified EVS personnel and IPs to guide and implement the appropriate environmental cleaning procedures and infection prevention and control measures. See **64. Ambulatory Surgery Centers** for more information.

Long-term Care Facilities

As the population continues to age and an increasing number of healthcare services are provided outside the hospital, the utilization of long-term care has evolved beyond the traditional concept of residential or custodial care. At the same time, an increasing number of long-term care facility (LTCF) residents are becoming colonized and infected with MDROs and *C. difficile*, leading to outbreaks associated with these pathogens. As colonized or infected individuals move between various levels of care and/or between care settings, the risk of potential cross contamination and/or transmission of infection increases.[56]

One of the major methods of preventing and controlling the spread of MDROs and CDIs is thorough environmental cleaning. The cleaning requirements in an LTCF must be described and monitored per facility policy. However, compliance can be problematic. A study of high-touch points in an LTCF showed that only 26.9 percent of the surfaces were cleaned and disinfected according to policies. With skilled leadership and persistent training, adherence eventually tripled. This improvement was due to strong leadership in EVS and infection prevention and control and effective training programs.[57]

Outpatient Settings

The CDC's guidelines for cleaning outpatient settings are similar to those for inpatient areas.[58]High-touch surfaces in the patient zone (examination rooms, procedure rooms, and waiting areas) must be cleaned and disinfected with an EPA-registered product. Floors may be cleaned with a detergent instead of a disinfectant unless contaminated with blood and body fluids. Because there are a minimum number of areas at risk for blood and body fluid spills, more carpeting may exist in this setting. Carpets should be vacuumed daily, spot cleaned as needed, and thoroughly cleaned on a routine schedule.

Waste should be collected daily. Because there is significantly less biohazardous waste in this setting, facilities may utilize one large biohazard container in a central location. However, a biohazardous waste

container must be available in procedure rooms.

Outpatient facilities must have written cleaning policies and procedures and provide training to staff who perform these functions. Facilities should assign responsibility for overseeing environmental cleaning and disinfecting to a qualified person.

Evaluating Effectiveness of Cleaning

The inanimate environment plays a role in the transmission of HAIs. Studies have shown that only 32 percent of more than 110,000 objects in inpatient and outpatient healthcare facilities are thoroughly cleaned.[2]Reasons for inadequate cleaning may include improper cleaning methods, lack of training, ineffective cleaning agents, and/or malfunctioning equipment. If a room is not thoroughly cleaned and disinfected, transmission of potential pathogens existing on environmental surfaces may occur. Therefore, it is important to evaluate the efficacy of cleaning.[7]

Visual Inspection

EVS personnel and their supervisors should inspect their completed work to ensure that visible evidence verifies that basic cleaning has been done. A written checklist can be helpful in assisting the inspection process. Visual assessments are helpful in determining if a room is aesthetically pleasing and in assessing whether the individual has completed his or her tasks but are not considered a reliable indicator of cleaning efficacy.[2]

ATP Bioluminescence Test

One way to evaluate cleaning efficacy is by using the adenosine triphosphate (ATP) bioluminescence method. In this method, swabs of environmental surfaces are placed in reagent and the amount of light is read by the bioluminometer. Results are indicated as either acceptable or unacceptable. The presence of ATP serves as a surrogate for microbial contamination. It does not identify actual pathogens. Furthermore, the level of ATP detected by bioluminescence has not been conclusively correlated with infection transmission.

Recently, the reliability of the ATP test used in healthcare has been challenged. Because each bioluminometer has its own scale, Whitely et al. questioned the lack of RLU standardization of the readings and the ability to compare results.[59]Rutala also showed that this method was not as accurate as fluorescent markers.[2]Although the test is easy to learn and may be performed quickly, the reagents, bioluminometer, and software to record the readings can be costly.

Fluorescent Markers

Another simple method to evaluate cleanliness is applying an invisible fluorescent mark onto soiled surfaces.[2'27'60]If the fluorescent mark is visible under a UV light after the surface is cleaned, the surface requires recleaning. The fluorescence is simple to apply, easy to remove, and inexpensive, and the results are known immediately after the cleaning has been completed. The mark is applied by dipping a swab in the fluorescent solution and touching the tip of the swab to a surface. A prepackaged fluorescent marking gel containing an applicator sponge is easier to use than a cotton swab and makes uniform circular marks but is only available if a computerized data collection system is also purchased.

When the fluorescence is applied without the knowledge of EVS or patient care providers findings have been extremely educational. Florescent marking can enable the IP or other supervisor to provide

immediate feedback to EVS personnel before they leave the area and show them the missed spots that need to be recleaned.

Cultures

Quantitative environmental cultures (swabs, Rodac plates) have been used as markers of thorough cleaning; less than 2.5 cfu/cm^2 is considered acceptable.[13]However, routine culturing of surfaces is not the first choice because it is costly, time-consuming, and results take at least 1 day. Environmental sampling may be performed when recommended by infection prevention and control. Cultures can be helpful in identifying the source of an outbreak.

Comparison of Methods

Rutala et al. compared the accuracy of the different methods for measuring the thoroughness of cleaning.[2]Colony counts on Rodac plates served as the gold standard. In the study, cultures found that 97.7 percent of surfaces studied were adequately clean. In contrast, the ATP bioluminescence indicated that 13.2 to 26.4 percent (depending on the RLU used) were properly cleaned; visual inspection showed that 43.8 percent were properly cleaned; and the fluorescent markers identified that 71.1 percent of surfaces were properly cleaned.

The swab and fluorescent method is the quickest and cheapest test. Most importantly, immediate feedback to personnel leads to more thorough recleaning. Carling et al. demonstrated that use of fluorescent markers and education improved cleaning from 48 percent (9,910 of 20,646 surfaces) to 77 percent (7,287 of 9,646 surfaces).[61]

Waste Management

Every healthcare institution has a solid waste disposal system that involves EVS. There are written policies and procedures for segregating and handling biohazardous waste, nonbiohazardous waste, chemical waste, radioactive waste, regular waste, and recyclable waste. Regardless of type, the institution is responsible for all waste, from creation to final disposal. In this chapter, only biohazardous and nonbiohazardous wastes are discussed. (Refer to **113. Waste Management**.)

Regulations for handling biohazardous waste differ by state. The appropriate state and local regulations governing the institution must be reviewed and followed. IPs must be familiar with these regulations, the institution's waste handling process, and responsibilities of waste haulers contracted to handle biohazardous and nonbiohazardous waste. Infection prevention and control should review documentation indicating that the waste hauler has met regulatory requirements. Because the facility is responsible for its biohazardous waste from creation to disposal, it is imperative that it is properly handled by both the institution and the hauler.

Definition of Biohazardous Waste

Biohazardous waste is also referred to as regulated, infective, infectious, and medical waste. OSHA defines biohazardous waste as[5]:

- Any liquid or semiliquid blood or other potentially infectious materials
- Contaminated items that would release blood or other potentially infectious materials in a liquid or semiliquid state if compressed

- Items that are caked with dried blood or other potentially infectious materials and are capable of releasing these materials during handling
- Sharps (includes needles, scalpel blades, glass, pipettes) contaminated with blood and body fluids
- Pathological and microbiological wastes containing blood or other potentially infectious materials

Definitions of biohazardous waste may differ depending on state and local regulatory agencies. For example, the Illinois Environmental Protection Agency classifies animal waste, isolation waste, and all sharps (used and unused), as biohazardous waste.[49]

Waste from isolation rooms is not considered biohazardous unless visibly contaminated with blood and other potentially infectious materials.[25]

Laboratory waste containing live cultures of microorganisms and agents of bioterrorism must be destroyed before transport out of the laboratory area. Live organisms have a potential for spreading. For example, an outbreak of TB occurred among personnel in a waste disposal facility because cultures of *M. tuberculosis*were aerosolized.[62]

Handling of Waste

Biohazardous and nonbiohazardous waste must be maintained in separate containers.[1,5,49]If wastes are inadvertently mixed, the nonbiohazardous waste is considered biohazardous.

Most biohazardous waste can be placed in a single leak-resistant red plastic bag or other color bag and labeled with a biohazard symbol. If punctured or contaminated, the bag is placed into a second bag. Bags must be securely closed when filled. Biohazardous waste containers not in continuous use, such as those in the soiled utility room, procedure room, or nursing station, must be kept covered.[1,5,49]

When biohazardous waste is stored, it is placed in a puncture-resistant, leakproof container that is labeled with a biohazard symbol or color-coded red.[5]The storage area must be well ventilated and inaccessible to rodents and other pests.[1]

Waste containers must be noncombustible. Those with a capacity greater than 20 gallons (76 liters) must be covered with lids composed of noncombustible materials.[63]

To prevent percutaneous injuries, personnel should never use their hands or feet to compress waste in containers. Plastic bags should be handled from the top and kept from contacting the body.

Sharps disposal containers must be puncture-resistant, leakproof at the sides and bottom, and closable.[1,5]They must be closed before they are overfilled. HCP must ensure that no sharps protrude from the opening of disposal containers.

Glass is regarded as a sharp and discarded in a puncture-resistant container. Glass containing blood or other potentially infectious materials is treated as biohazardous waste. Some states and some local regulatory agencies consider uncontaminated glass as biohazardous waste.[49]

Broken glass is never handled, even if hands are gloved. Broken pieces should be picked up and discarded by devices such as forceps or by a brush and dustpan or two pieces of cardboard. If contaminated, the device must be decontaminated or discarded.

Waste bags must be secured and closed before transport. Nonbiohazardous waste can be placed in a chute, if available, or kept in a temporary holding room such as a designated "soiled" utility room. Biohazardous waste should never be placed into a chute because of the possibility of rupture or leakage. Biohazardous waste must be transported in securely covered containers to the temporary holding room.

Although there are no guidelines specifying the frequency for cleaning chutes, they should be cleaned on a routine schedule (usually at least daily) and whenever spills occur. The waste holding room should be cleaned at least daily and restricted to EVS employees. The degree of restriction (e.g., locks on doors) varies by local health regulations. Waste should be removed from chute rooms and holding rooms at least daily and sent for final disposal.

Traditionally, biohazardous waste has been either incinerated or steam sterilized. Alternatives to incineration and steam sterilization have been developed and facilities must be carefully evaluate them to determine their acceptability. Incinerators, autoclaves, or other treatment devices must meet all local, state, and federal regulatory agency requirements. Pathologic wastes must be incinerated.

Reusable biohazardous waste containers must be disinfected by the waste hauler with an EPA-registered disinfectant before they are returned to the healthcare institution for use.

Pest Control

The presence of cockroaches, flies, maggots, ants, mosquitoes, mice, rats, bed bugs, and other pests is an indicator of an unhealthy environment in a healthcare facility. Institutions are responsible for minimizing, and if possible eliminating, vermin. The key to minimizing pests is to eliminate food sources, eliminate areas for nests and burrows, install tightly fitting screens on windows and doors, seal off penetrations to the outside, and apply pesticides. Food should not be left out in the open, eating areas should be cleaned frequently, and food waste should be discarded in sealed containers. It takes diligence to control pests, especially bed bugs.

Bed bug control is more costly than other types of pest control.[64] The exterminator needs to make multiple visits and may use a variety of chemicals, expensive high heating devices, and/or a specially trained dog. As of the publication of this book, the heating device for eliminating bed bugs costs approximately $15,000 and a bed bug sniffing dog costs $600 per visit.

EVS is usually responsible for coordinating pest control. Although EVS personnel play a major role in minimizing pests, facilities should consider contracting licensed professionals to handle toxic pesticides. Should the facility decide to have internal employees handle pesticides, these individuals must be licensed and adhere to regulatory requirements (OSHA, state, and local). They must be educated and trained about the chemicals used, the appropriate PPE needed, and when, where, and how to use the pesticides.

Impact of Design on Environmental Contamination

Although institutions have made great strides in creating a warm and welcoming atmosphere by using colorful and patterned fabrics on curtains, furniture, and carpeting; hanging restful pictures; and painting walls various colors, building an environment that minimizes infections is an emerging discipline.[65] Both the EVS manager and IP need to have an understanding of how elements of these new designs impact EVS policies and procedures including associated risks, time requirements, and the need for specialized training or equipment and associated cost.

To help prevent cross-transmission of infections, new healthcare constructions are required to have a full bathroom in each single inpatient rooms.[66] Institutions that provide family-focused care should expect that patients' relatives may stay overnight, and these institutions may consider extending visiting hours. The increased footage for private rooms and bathrooms and presence of overnight guests can create more work for EVS at a time when budgets are forcing reductions in the workforce.

To encourage hand hygiene, sinks must be located so that clinicians can face patients and ABHR dispensers should be placed in line sight of clinicians. With increasing use of hand hygiene agents, EVS personnel need to check and restock dispensers and to clean stains on the walls and floors more frequently.

Many newer textiles (mops, curtains, upholstery, and carpeting) are more durable to bleach and other harsh chemicals. They may also be coated with antimicrobial materials such as metal alloys, quats, and triclosan. Studies have shown that incorporating silver alloys into privacy curtains reduces the microbial contamination of the curtains.[43,44] This may decrease the frequency needed for changing these curtains.

Because triclosan and quats are germicides, there is a risk for organisms to develop resistance. *P. aeruginosa* is intrinsically resistant to triclosan.[67]

Silver and copper have been incorporated into some hard environmental surfaces and shown to minimize the growth of microorganisms. The effectiveness of silver on hard surfaces in reducing HAIs has not been adequately studied in healthcare.[67] However, Salgado et al. found that copper not only reduced the microbial counts on surfaces but also the HAI rate.[68] Incorporating copper into the bed rails, overbed tables, intravenous poles, and arms of visitor chairs in intensive care units at three hospitals reduced the HAI rate from 0.081 to 0.034 (p= 0.013).

Creating a sharklike pattern on high-touch surfaces has also been shown to be antimicrobial. This pattern consists of millions of microscopic diamonds arranged in a pattern that mimics shark skin and prevents bacteria from colonizing and creating a biofilm.[69] Researchers speculate that the pattern requires too much energy for the bacteria to colonize. To date, this technology has not been applied to healthcare.[67]

Operating Budget

The EVS departmental operating budget consists of two major components: (1) salaries and wages and (2) supplies. With the increasing cost of healthcare and reduction in reimbursement for care provided, healthcare administrators are cutting departmental budgets and positions. EVS is often affected and needs strong leaders who can meet these challenges. These leaders can create novel ways to save money while providing the services demanded. At the same time, these directors, managers, and supervisors can offer training, support, and guidance to employees that stem from a wide range of backgrounds.

The number of full-time equivalents (FTEs) assigned to EVS may be based on the square footage of the facility, the responsibilities of the department, and existing conditions. If EVS is responsible for the care of the grounds surrounding the facility, then the square footage of the land requiring care (mowing grass, removing snow, etc.) is included in the calculations. Inside duties vary by assignment. Cleaning an isolation room requires more time than cleaning a regular patient room. Likewise, cleaning the operating room is more demanding than cleaning the corridor. There also needs to be personnel sufficient to handle emergencies, such as an outbreak of gastroenteritis or *C. difficile*, and to prepare for

special occasions (e.g., surveys by regulatory agencies or TJC, etc.). Assignments for each EVS employee should be carefully planned to maximize productivity with a minimal number of personnel.

Cross-training employees on tasks creates a more versatile EVS department and makes scheduling and assignments easier. For example, personnel may be trained to clean patient rooms and clinics, as well as offices, laboratories, corridors, and operating rooms. Alternatively, they may be cross-trained to wash walls, deep scrub and polish floors, shampoo carpets, and handle waste.

To further maximize efficiency and productivity, supervisors should provide each EVS employee with the daily work flow, establish departmental expectations for the time to complete the tasks, and oversee the work. The goals for turnaround times (between cases in the operating rooms, for cleaning patient rooms) should be realistic. For example, 30 minutes may be the expected turnaround time between cases in the operating rooms and after a patient is discharged or transferred from an inpatient room. If more time is needed, the reasons should be documented and evaluated. EVS supervisors can then make necessary improvements, such as providing re-education programs for staff or allocating more time for similar situations in the future.

Cleaning products and supplies should be evaluated and selected based on effectiveness and cost savings. Items purchased in bulk through a major supplier or through a healthcare consortium are cheaper than when purchased by an individual department or a single facility. EVS may also consider using generic and environmentally friendly products. EVS supervisors should consult with the infection prevention and control team and other personnel outside of the department with expertise about products. If EVS considers saving money by using detergents instead of disinfectants on floors or regular hand-washing soaps rather than antiseptics, EVS should collaborate with the infection prevention and control team prior to implementing the practice.

EVS supervisors must take care to avoid compromising the quality of work to meet budgetary demands. Preventing the environment from being a source of HAIs is crucial for both patient safety and cost savings. The cost of one of the following HAIs is greater than the salary of some EVS employees: catheter-associated bloodstream infection ($45,814), ventilator-associated pneumonia ($40,144), surgical site infection ($20,785), and CDI ($11,285).[70]

EVS Hygiene, Attire, and Behavior

EVS personnel are expected to have good personal hygiene and appearance. They should be educated to bathe daily, contain their hair so it does fall onto their faces and work area, and practice meticulous hand hygiene. Supervisors should make informal or formal inspections on personnel hygiene and appearance. Supervisors can partner with the infection prevention and control department to conduct period observations of hand hygiene compliance (see Table 107-2).

Table 107-2 PROCEDURE FOR MONITORING HAND HYGIENE AND ISOLATION COMPLIANCE

Directions for Hand Hygiene Observations:

1. Observe EVS personnel working in a patient care area.

2. Examples of when EVS personnel should perform hand hygiene:

a. Before gloving and entering a patient's room to clean.

b. After cleaning a patient's room and gloves were removed.

c. Before handling clean lining.

d. After bagging soiled linen and placing it in the linen cart.

e. After collecting and bagging trash and placing it in trash cart.

f. After handling soiled cleaning equipment (mops, cloths, buckets).

g. After using the bathroom.

h. Before and after eating or going on a break.

3. Document compliance or noncompliance with hand hygiene. One person can be observed for multiple opportunities to perform hand hygiene.

4. Make at least 20 observations per month per unit (equivalent to 1 observation per day if working an 8-hour shift).

5. Compliance = use of alcohol hand rub or soap and water to wash hands. Length of time hands are washed will not be a factor.

6. At the end of each month, calculate the compliance rate. After obtaining 3 months of data, make a graph. Infection prevention and control may assist with this task.

a. Denominator = number of observations.

b. Numerator = number of individuals compliant with hand hygiene.

c. Compliance rate = number of individuals compliant with hand hygiene / number of observations X100.

7. Share data with the staff in EVS, infection prevention and control, infection prevention and control committee, and other hospital committees and leadership groups.

8. EVS supervisors should re-educate noncompliant individuals, especially repeat offenders on hand hygiene.

Observing compliance with Isolation Precautions is conducted in the same manner. The need for gowning, gloving, and masking will depend on the isolation category. The individual entering an isolation room can be observed for compliance with both Isolation Precautions and hand hygiene. Again, noncompliant personnel should be educated on the importance of adherence with Isolation Precautions.

Most healthcare facilities issue uniforms to EVS personnel, instruct them on how to launder them, and require them to wear a clean uniform each work day. Uniforms serve to identify EVS personnel for patients, visitors, and other employees.

If EVS personnel work in departments that require scrub attire, they must be educated about regulations regarding how and where scrubs may be worn. Scrubs for the operating rooms and other procedural areas may not be worn home or out of the hospital, and they are laundered by a licensed laundry facility.

Personnel should also be trained in proper behavior when interacting with patients, visitors, and other HCP. They should be instructed to knock on doors before entering, to greet people, and to interact with others courteously. Their behavior can affect patient and HCP satisfaction, an important component of the success of the facility.

Education and Training

All new employees must undergo a documented orientation session. Although most regulatory agencies require only annual education on infection prevention and control, more frequent programs are recommended.

Educational Topics

Orientation programs include at least the following: OSHA's Bloodborne Pathogens Standard, Hazard Communication Standard (revised 2013), TB control, cleaning techniques, cleaning agents, isolation precautions, N95 particulate respirators, personal attire and hygiene, and behavior.[71]Subsequent training programs address and review bloodborne pathogens, hazard communication, TB control, *C. difficile*, pest control (including cockroaches, rodents, and bed bugs), gastrointestinal outbreaks, EVS problems identified by regulatory agencies, cleaning methods, new products and equipment, Isolation Precautions, special topics (aspergillosis in immunosuppressed patients and latex allergies), weaknesses identified by continuous quality improvement, and competency testing programs.

Education programs should also cover the health and hygiene of individuals. Personnel with symptoms of highly communicable diseases (fever, fever and flulike symptoms, fever and rash of unknown etiology, diarrhea, conjunctivitis, and exposed open draining lesions) should be instructed to stay home. The importance of complying with screening for TB, obtaining specific vaccinations (influenza, Hepatitis B, tetanus, pertussis, rubella, rubeola, and chickenpox), and adhering with postexposure follow-up should be emphasized.

Educational Levels and Proficiency in English

Educational programs should be appropriate to the personnel. EVS personnel often have the lowest education level among HCP. In 2007, the U.S. Census Bureau showed that 28 percent of "janitors and building cleaners" aged 25 years or over did not have a high school diploma, and 12.3 percent had 9 years or less of education.[72]

The lack of education can be compounded by an increasing number of individuals who are not proficient in English. From 1980 to 2010, there was a 158 percent increase of Americans over age 5 (almost 60 million people) who lived in homes where a language other than English was spoken. In comparison, during this same time period, there was only a 22 percent increase in the proportion of Americans over age 5 living in households where only English was spoken.[73]Among the 166.1 million Americans aged 25 and over who spoke only English at home, 9.6 percent had less than a high school education, but among the 42.7 million people aged 25 and over who spoke a language other than English at home, 29.2 percent lacked a high school diploma.[74]There has been a significant growth in the number of non-U.S.-born workers in the U.S. civilian labor force.[75,76]

The lack of formal education correlates with low levels of health literacy and understanding the rationale for cleaning policies and procedures, such as for isolation rooms.[77,45]If the reasons for cleaning are not understood, thoroughness of cleaning suffers, and the environment becomes a source of cross-transmission of infections. Subsequent HAIs lead to undesirable patient outcomes and increased healthcare cost.

Educational Methods

To enhance learning, it is important to use multiple educational methods such as visual aids, return demonstrations, repetition, and hands-on training. Interpreters may be provided for individuals not

proficient in English but who are able to perform the job. Small groups allow more interaction and are often more effective than large ones.

After an education session, each individual should demonstrate competency, which can be done in a variety of ways. If literacy and/or proficiency in English are not a problem, a written test can be administered. Alternatively, an oral test can be given. Personnel may also be asked to provide a return demonstration. Return demonstrations can be a means of overcoming educational and language barriers. Testing the thoroughness of cleaning is another measure of competency. If an individual is unable to demonstrate competency after an education session, further education and training should be provided.

Education programs should be documented in the following manner:

- Name of employee and his/her identification number
- Name of the presenter
- Qualifications of the presenter, if required (e.g., by OSHA's bloodborne pathogens standard)
- Brief outline of the presentation
- Date and location of the program
- Documentation of the employee's competency.

Frequent re-education programs on the same topics, especially thoroughness of cleaning for high-touch surfaces, may be beneficial.

Performance Improvement Programs

Every EVS department should have ongoing performance improvement programs (also referred to as quality improvement). EVS leadership should develop evaluation tools to study and measure their activities. Thresholds or benchmarks should be established and data collected and analyzed. The findings determine the necessary improvements.

There are numerous topics for performance improvement activities. Determining the thoroughness of cleaning is generally the highest priority. Other studies include meeting turnaround times, appropriate use of PPE, adhering to Isolation Precautions, complying with hand hygiene, and evaluating staff knowledge of cleaning policies and procedures. Personnel may also be evaluated for using cleaning products properly, following procedures after exposure to blood and other potentially infectious materials or hazardous chemicals, and obtaining the influenza vaccination.

Much emphasis has been placed on minimizing turnaround time and maximizing efficiency with fewer EVS personnel and a reduced budget. These performance improvement projects serve as important barometers to ensure the quality of work is not compromised by these reductions.

One of the most effective steps to improving quality is providing feedback on performance improvement findings to staff as soon as possible. For example, one study showed that when results of a fluorescent test were shared with personnel, the thoroughness of cleaning increased from 48 percent to 77 percent.[61]

Summary And Conclusions

There is increasing evidence that the environment of a healthcare facility serves as a source of HAIs. An effective EVS program prevents the environment from becoming a reservoir of microorganisms. This is achieved by establishing regular cleaning schedules, outlining thorough and effective cleaning methods, writing policies and procedures, selecting appropriate cleaning agents and equipment, educating and training EVS personnel, and monitoring the thoroughness of cleaning. Infection prevention and control and EVS should partner with each other and other healthcare personnel to achieve these goals.

Future Trends

For many centuries, caustic and toxic substances such as carbolic acid and lye were used to clean healthcare institutions. Over the years, equally effective but safer and less harmful disinfectants have been developed. In the 1980s and early 1990s, manufacturers made disinfectants effective against HIV and viral hepatitis. During the next decade, chemists found a way to reduce the long contact times for tuberculocidal disinfectants. Researchers recently created an effective hydrogen peroxide disinfectant that is not highly toxic or corrosive, has minimal odor, and claims the fastest killing time for bacteria and viruses. If effective, its use will increase dramatically in healthcare. As new diseases and microorganisms emerge (SARS, Middle East respiratory syndrome, coronavirus, monkeypox, MDROs, *C. difficile*), testing the efficacy of cleaning against new pathogens and developing new, easier, and more effective disinfectants continues to present a challenge.

Over the years, new products and novel technologies have improved the efficiency and efficacy of cleaning. Some of these inventions include chemical dispensers delivering premixed and premeasured amounts of solutions, microfiber textiles, detachable mop handles with attachments for dispensing cleaning agents, vacuum cleaners with HEPA filters, autoscrubbers, and other floor cleaning machines. Within the past few years, great strides have been made in reducing antimicrobial contamination on high-touch surfaces by impregnating silver into textiles and incorporating copper into hard surfaces. UV light and hydrogen peroxide vapors are novel methods used to ensure maximum cleanliness of the environment after physical cleaning. An increasing number of hospitals are exploring and adopting these new technologies.

In spite of the technological developments, adherence to good, basic environmental cleaning practices remains the biggest challenge. The key to meeting this challenge is education of HCP, strong leadership, and good communication between EVS, infection prevention and control, and other departments.

Appendix

Definitions of Cleaning and Disinfection Terminology

Antimicrobial agent: any agent that kills or suppresses the growth of microorganisms.

Antiseptic: substance that prevents or arrests the growth or action of microorganisms by inhibiting their activity or by destroying them. The term is used especially for preparations applied topically to living tissue.

Bactericide: agent that kills bacteria.

Contact time: time a disinfectant is in direct contact with the surface or item to be disinfected. For surface disinfection, this period is framed by the application to the surface until complete drying has occurred.

Contaminated: state of having actual or potential contact with microorganisms. As used in healthcare, the term generally refers to the presence of microorganisms that could produce disease or infection.

Cleaning: removal, usually with detergent and water or enzyme cleaner and water, of adherent visible soil, blood, protein substances, microorganisms, and other debris from the surfaces, crevices, serrations, joints, and lumens of instruments, devices, and equipment by a manual or mechanical process that prepares the items for safe handling and/or further decontamination.

Culture: growth of microorganisms in or on a nutrient medium; to grow microorganisms in or on such a medium.

Decontamination: according to OSHA, "the use of physical or chemical means to remove, inactivate, or destroy bloodborne pathogens on a surface or item to the point where they are no longer capable of transmitting infectious particles and the surface or item is rendered safe for handling, use, or disposal" [29 CFR 1910.1030]. In healthcare facilities, the term generally refers to all pathogenic organisms.

Detergent: cleaning agent that makes no antimicrobial claims on the label. They comprise a hydrophilic component and a lipophilic component and can be divided into four types: anionic, cationic, amphoteric, and nonionic.

Disinfectant: usually a chemical agent (but sometimes a physical agent) that destroys disease-causing pathogens or other harmful microorganisms but might not kill bacterial spores. It refers to substances applied to inanimate objects. The EPA groups disinfectants by product label claims of "limited," "general," or "hospital" disinfection.

Disinfection: thermal or chemical destruction of pathogenic and other types of microorganisms. Disinfection is less lethal than sterilization because it destroys most recognized pathogenic microorganisms but not necessarily all microbial forms (e.g., bacterial spores).

EPA Registration Numberor **EPA Reg. No.**: a hyphenated, two- or three-part number assigned by EPA to identify each germicidal product registered within the United States. The first number is the company identification number, the second is the specific product number, and the third (when present) is the company identification number for a supplemental registrant.

Germicide: agent that destroys microorganisms, especially pathogenic organisms.

Inanimate surface: nonliving surface (e.g., floors, walls, furniture).

Infectious microorganisms: microorganisms capable of producing disease in appropriate hosts.

Intermediate-level disinfectant: agent that destroys all vegetative bacteria, including tubercle bacilli, lipid and some nonlipid viruses, and fungi, but not bacterial spores.

Low-level disinfectant: agent that destroys all vegetative bacteria (except tubercle bacilli), lipid viruses, some nonlipid viruses, and some fungi, but not bacterial spores.

Log reduction in bacteria: Log means logarithm, which is the exponent of 10. A 1-log reduction stands for a 10-fold (one decimal) or 90 percent in numbers of live bacteria. For example 100 bacteria would

be reduced to 10. A 3-log reduction on a surface with 1,000,000 microbes would leave 1,000 organisms, which equates to a 99.9 percent reduction.

Microorganisms: animals or plants of microscopic size. As used in healthcare, generally refers to bacteria, fungi, viruses, and bacterial spores.

Mycobacteria: bacteria with a thick, waxy coat that makes them more resistant to chemical germicides than other types of vegetative bacteria.

One-step disinfection process: simultaneous cleaning and disinfection of a noncritical surface or item.

Personal protective equipment (PPE): specialized clothing or equipment worn by an employee for protection against a hazard. General work clothes (e.g., uniforms, pants, shirts) not intended to function as protection against a hazard are not considered to be PPE.

Quat: abbreviation for *quaternary ammonium compound*, a surface-active, water-soluble disinfecting substance that has four carbon atoms linked to a nitrogen atom through covalent bonds.

Safety data sheet (SDS)(formerly known as material safety data sheet or MSDS): information document on substance to ensure that individuals handle and/or use it safely. Information on the sheet includes physical data (melting point, boiling point, flash point), toxicity, health effects, first aid reactivity, storage, disposal, PPE, and procedures for handling spills. Every EPA-registered cleaning agent has an SDS.

Sanitizer: agent that reduces the number of bacterial contaminants to safe levels as judged by public health requirements. Commonly used with substances applied to inanimate objects. According to the protocol for the official sanitizer test, a sanitizer is a chemical that kills 99.999 percent of the specific test bacteria in 30 seconds under the conditions of the test.

Spore: relatively water-poor round or elliptical resting cell consisting of condensed cytoplasm and nucleus surrounded by an impervious cell wall or coat. Spores are relatively resistant to disinfectant and sterilant activity and drying conditions (specifically in the genera *Bacillus*and *Clostridium*).

Sterileor **sterility**: state of being free from all living microorganisms. In practice, usually described as a probability function (e.g., as the probability of a microorganism surviving sterilization being one in one million).

Tuberculocide: an EPA-classified hospital disinfectant that also kills *M. tuberculosis*(tubercle bacilli). EPA has registered approximately 200 tuberculocides. Such agents also are called *mycobactericides*.

Use-life: the length of time a diluted product can remain active and effective. The stability of the chemical and the storage conditions (e.g., temperature and presence of air, light, organic matter, or metals) determine the use-life of antimicrobial products.

Vegetative bacteria: bacteria that are devoid of spores and usually can be readily inactivated by many types of germicides.

Virucide: an agent that kills viruses to make them noninfective.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Laboratory Services

Author(s): Peggy Prinz Luebbert, MS, MT(ASCP), CIC, CHSP
Healthcare Interventions, Inc.

Omaha, NE

Published: October 3, 2014

Abstract

Infection preventionists should look at the laboratory setting from two perspectives. First, laboratorians are at high risk of occupational infections, and there must be specific policies and procedures in place to protect them from organisms in their unique environment. Second, the laboratory is an essential partner of infection preventionists in assisting in the detection and characterization of pathogens, not only for healthcare-associated infections but also for organisms associated with research, community, or bioterrorism outbreaks.

Key Concepts

- The laboratory is a unique work environment that may pose infectious disease threats to those who work there.
- Multiple federal, state, and private agencies provide guidelines and regulations to assist in ensuring the safety of the laboratory environment.
- The most common primary accreditation agency for laboratories is the College of American Pathologists.
- Biosafety levels were established to ensure that the laboratory environment is adequately equipped with measures to ensure the safety of those working in them or the surrounding environment.
- Special procedures are used to ensure the safe handling and transport of biohazardous materials.
- Being one of the largest generators of infectious waste in the healthcare setting, specific procedures exist for laboratory infectious waste management.
- The Laboratory Response Network has been established in the United States as a diverse and collaborative system to provide rapid diagnosis and response in the case of a bioterrorism event or related public health emergency.
- The laboratory's role in the infection prevention program is fundamental.

Background

Laboratories are special, often unique, work environments that present identifiable infectious disease risks to persons in or near them. Laboratory-acquired infections have been reported since early in the 20th century, but only in the 1970s were accurate data available to try to validate risk.[1,2,3,4,5,6] In a series of published surveys, Pike and associates reported over 3,000 cases of laboratory-acquired infections (LAIs), including brucellosis, tuberculosis, typhoid, streptococcal infections, and hepatitis.[5,6]

These incidents and more current studies suggest that most laboratory-acquired infections occur when the mode of transmission is unknown or as a result of error, accident, or carelessness in the handling of a clinical specimen or known pathogen.[6]

Many federal and state agencies and private organizations in the United States have developed specific guidelines to assist in minimizing the transmission of infectious agents in the laboratory. These include:

- Clinical Laboratory Standards Institute (CLSI), formerly the National Committee for Clinical Laboratory Standards (NCCLS)[7,8,9,10,11,12,13,14,15,16,17]
- Occupational Safety and Health Administration (OSHA)[18]
- Centers for Disease Control and Prevention (CDC)[19,20]
- Food and Drug Administration (FDA)[21]
- American Association of Blood Banks (AABB)[22]
- The College of American Pathologists (CAP)[23]
- Biosafety in Microbiological and Biomedical Laboratories (BMBL)[24]
- American Society for Microbiology (ASM) (refer to Supplemental Resources)

INFECTION PREVENTION TEAM MEMBER

Laboratorians should be an integral part of an infection prevention program. The microbiology laboratory helps to detect and identify microorganisms so that the infection control team can monitor, prevent, and control infection transmission. The laboratorian assists clinicians in diagnosing and determining treatment options. In addition to performing these traditional roles, a laboratory representative should participate as a member of the healthcare organization's infection prevention and control committee. Responsibilities of the laboratorian for the organization and on the infection prevention and control committee may include:

- Explaining basic microbiology principles and practices
- Interpreting culture results and explaining which microbiological approaches could be used to solve specific infection control problems
- Explaining the advantages and limitations, the scope and adequacy, and the costs of microbiological methods used to detect, identify, and assess the antimicrobial susceptibility of the most common pathogens implicated in healthcare-associated infections (HAIs)
- Providing information about changes in methods, reagents, or instrumentation that may substantially affect the laboratory's ability to detect and characterize pathogens that may cause HAIs

- Actively participating in surveillance efforts while planning and executing microbiological and molecular epidemiological investigation of HAIs
- Providing an annual antibiogram of common organisms and the trending associated with resistance patterns of clinical isolates to antibiotics

The laboratory and the infection prevention staff must communicate regularly to be effective. Infection preventionists (IPs) should regularly make rounds in the laboratory to ask questions, review microbiological and molecular epidemiological results, and discuss current issues. Additionally, laboratory staff should become active in infection prevention conferences offered by the Association for Professionals in Infection Control and Epidemiology (APIC) to remain current on issues and concerns that may relate to the laboratory.

Basic Principles

ACCREDITATION

The Centers for Medicare & Medicaid Services (CMS) regulates all laboratory testing (except research) performed on humans in the United States through the Clinical Laboratory Improvement Amendments (CLIA). In most states, CLIA accreditation occurs annually by local state surveyors. CLIA has given deeming authority to a small group of accreditation organizations, including AABB, the American Osteopathic Association (AOA), the American Society for Histocompatibility and Immunogenetics (ASHI), CAP, Commission on Office Laboratory Accreditation (COLA), and the Joint Commission (TJC). A few states with state licensure programs have also received exemption from CLIA program requirements.

Most hospital-based laboratories are accredited by the CAP. These laboratories are typically reviewed every 2 years by a team of peer laboratorians. The CAP inspection process is recognized by TJC, and often TJC will do only a cursory laboratory survey if the laboratory has an up-to-date CAP accreditation. Several months prior to the anticipated inspection, the CAP will send the laboratory a self-scoring checklist to complete and return. Each question on the checklist is given a phase category that corresponds to a type of deficiency. Phase 0 questions are for information only. Phase I questions represent items that are considered important for the management of an outstanding laboratory service; Phase I deficiencies *should*be corrected. Phase II questions represent items of major importance that are essential to the management of a laboratory. Phase II deficiencies are major defects that *must*be corrected before accreditation can be granted. Examples of Phase I and II questions can be obtained from the CAP.[23]

Principles of Laboratory Testing

BIOSAFETY LEVELS

During the 1970s, in an effort to diminish the risks of LAIs, scientists devised a system for categorizing etiological agents into groups based on their mode of transmission, the type and seriousness of illness resulting from infection, availability of treatment (e.g., antimicrobial drugs), and availability of prevention measures (e.g., vaccination). These etiological agent groupings were the basis for development of guidelines for appropriate facilities, containment equipment, procedures, and work practices to be used by laboratory workers. The BMBL guidelines refer to Biosafety Levels (BL) 1 through 4. The BMBL guidelines are published and regularly reviewed and updated by the U.S. Department of Health &

Human Services (HHS), Public Health Services, CDC, and the National Institutes of Health (NIH); they have become the "code of practice for biosafety" in the laboratory setting.[24]

Four Biosafety Levels are also described for activities involving infectious disease research with experimental animals. These four combinations for practices, safety equipment, and facilities are designated Animal Biosafety Levels 1, 2, 3, and 4 and are similar to standard Biosafety Levels.

Biosafety Level 1

Biosafety Level 1 (BL-1) defines conditions suitable for work involving well-characterized microorganisms not known to cause disease in healthy adult humans and of attendant minimal potential hazard to laboratory personnel and the environment. Undergraduate and secondary training/teaching laboratories and some physicians' office laboratories can be categorized as BL-1. These laboratories may not necessarily be separated from the general traffic patterns in the building, and work is generally conducted on open benchtops using standard practices. Special containment equipment or facility design is neither required nor generally used. Laboratory personnel have specific training in the procedures conducted in the laboratory and are supervised by a scientist with general training in microbiology, medical technology, or related sciences. Infection prevention measures for BL-1 include hand hygiene when indicated.*Bacillus subtilis, Naegleria grubri*, and infectious canine hepatitis virus are representative of organisms that may be handled in a BL-1 lab.

Biosafety Level 2

Biosafety Level 2 (BL-2) is similar to BL-1 and is suitable for work involving agents of moderate potential hazard to personnel and the environment. This safety level is appropriate when work is done with any human blood, body fluids, or tissues in which the presence of an infectious agent may be unknown. Unlike Level 1, BL-2 laboratory personnel have specific training in handling pathogenic agents and are directed by competent scientists. Access to the laboratory is limited when work is being conducted, and the laboratory is generally away from general traffic areas. Certain procedures in which infectious aerosols or splashes may be created are conducted in a biologic safety cabinet (BSC) or with other physical containment equipment, and extreme precautions are taken with contaminated sharps. (Also see **113. Waste Management**.)

Except in extraordinary circumstances (e.g., suspected outbreak of hemorrhagic fever), the initial processing of clinical specimens and identification of isolates can be done safely in a BL-2 laboratory. A lab with this designation is equipped to perform the recommended level of testing for bloodborne pathogens such as Hepatitis B virus (HBV) and human immunodeficiency virus (HIV). Containment elements are consistent with OSHA's Bloodborne Pathogen Standard (hand hygiene and appropriate personal protective equipment), as well as those recommended by the NCCLS ruling M29. (Although NCCLS was replaced by the Clinical and Laboratory Standards Institute [CLSI] in 2005, the publication title may still include the NCCLS designation.) HBV, *Salmonella*spp., and *Toxoplasma*spp. are representative of the microorganisms assigned to this containment level.

There is no specification for single-pass directional inward flow of air from a BL-2 laboratory. However, most microbiology laboratories also work with potentially hazardous chemicals. There are published recommendations for preventing buildup of chemical vapors in laboratories. This can be accomplished by using a chemical fume hood and/or having single-pass air when recirculation would increase ambient concentrations of hazardous materials. (Also see **114. Heating, Ventilation, and Air Conditioning**; and Chapter **116 Construction and Renovation**.)

Biosafety Level 3

Biosafety Level 3 (BL-3) is applicable to clinical, diagnostic, teaching, research, or production facilities in which work is done with indigenous or exotic agents; such agents may cause serious or potentially lethal disease as a result of exposure by the inhalation route. Often a BL-3-designated laboratory is located within a BL-2 containment laboratory; that is, the microbiology department is inside the general clinical laboratory. Laboratory personnel must have specific training in handling pathogenic, potentially lethal agents, and must be supervised by competent scientists who are experienced in working with such agents. *Mycobacterium tuberculosis*, St. Louis encephalitis virus, and *Coxiella burnetii*are representative of microorganisms transmissible by the aerosol route that are assigned to this level. Primary hazards to personnel working with these agents relate to exposure to infectious aerosols, autoinoculation, and ingestion.

In BL-3 laboratories, greater emphasis is placed on primary and secondary barriers. These barriers protect personnel in contiguous areas and the wider community from exposure to potentially infectious aerosols and to prevent contamination of the environment. The laboratory has special engineering and design features to provide a controlled environment targeted at managing infectious aerosols. A BL-3 laboratory is separated from other parts of the building by an anteroom with two sets of doors or by access through a BL-2 area. Because of the potential for aerosol transmission, air movement is unidirectional into the laboratory (i.e., from clean areas into the BL-3 area), and all air exhausted from the BL-3 area is directed outside the building without recirculation or is recycled using a high-efficiency particulate air (HEPA) filtration system. All procedures within a BL-3 involving manipulation of infectious materials are conducted within BSCs or other physical containment devices. Personnel must wear appropriate personal protective clothing and equipment while in a BL-3 laboratory and perform hand hygiene when indicated.

BL-3 facilities have solid floors and ceilings and sealed penetrations. They are designed and maintained to allow appropriate decontamination in the event of a significant spill. BL-3 laboratories have single-pass air (nonrecirculating air ventilation systems) to protect personnel. Filtration of exhaust air through HEPA filters is neither required nor recommended in most situations unless the air must be recirculated. Single-pass air that mixes with outside air allows for the rapid dilution of the small numbers of microorganisms that may be released in the laboratory. All waste from a BL-3 laboratory must be rendered noninfectious before final disposal.

Biosafety Level 4

Biosafety Level 4 (BL-4) laboratories are the most sophisticated of laboratories and are required for work with dangerous and exotic agents that pose a high risk of aerosol transmission for life-threatening diseases such as those caused by Marburg and Ebola viruses. Within work areas of the facility, all activities are confined to Class III or II BSCs used by workers wearing one-piece positive-pressure body suits ventilated by a life-support system. Members of the laboratory staff have specific and thorough training in handling extremely hazardous infectious agents. Staff understand the primary and secondary containment functions of standard and special practices, containment equipment, and laboratory design characteristics. The workers are also supervised by competent scientists trained and experienced in handling these agents. All waste is decontaminated before leaving the BL-4 laboratory, and air is exhausted from the BL-4 area through HEPA filters. These types of laboratories are rarely found within a hospital and are typically found in reference and/or research settings.

Biological Risk Assessment

Each clinical laboratory should perform a biological risk assessment on an annual basis or any time a new risk is identified.A biological risk assessment is a process used to identify the hazardous characteristics of a known infectious or potentially infectious agent or material, the activities that can result in a person's exposure to an agent, the likelihood that such exposure will cause an LAI, and the probable consequences of such an infection.

Fundamentally, the primary factors in the risk assessment and selection of precautions fall into two broad categories: agent hazards and laboratory procedure hazards. Although there is no standard approach for conducting a biological risk assessment, the BMBL document suggests a five-step approach to prevent LAIs:

1. *Identify agent hazards and perform an initial assessment of risk.*A review of potential biological agents and their hazardous characteristics should be completed. Hazardous characteristics include their capability to infect and cause disease in a susceptible human host, severity of disease and the availability of preventive measures, and effective treatments. The CDC and the Animal and Plant Health Inspection Service (APHIS) have implemented regulations that govern the possession, use, and transfer of these types of biological agents and toxins that have the potential to pose a severe threat to public health and safety. These agents/toxins are classified as "select agents." Such agents/toxins are registered and updated on a biennial basis by APHIS and a list of these agents, along with the regulations on how to handle them, can be found under the National Select Agent Registry Program; refer to Supplemental Resources in this chapter.

   In the typical clinical/hospital laboratory that is not doing research on these agents/toxins, special procedures must be implemented if one of these agents is identified from a patient culture (i.e., *Francisella tularensis*). For example, all waste and culture supplies, etc., that are contaminated with the select agent must be autoclaved prior to leaving the facility. Additionally, the APHIS/CDC Form 4 "Report of Identification of a Select Agent or Toxin in a Clinical or Diagnostic Laboratory" must be completed and mailed or faxed to APHIS or the CDC within 7 calendar days after identification of a select agent(s) or toxin(s) in a diagnostic specimen. Each laboratory should communicate regularly with their local health departments for the appropriate protocols to follow when identifying a select agent.

   The BMBL also has agent summary statements to help identify known and suspected routes of transmission of an LAI and, when available, information on infective dose, host range, agent stability in the environment, protective immunizations, and attenuated strains of the agent.

   The Control of Communicable Diseases Manual can provide information on various diseases including concise summaries on severity, mode of transmission, and the susceptibility and resistance of humans to disease; refer to Supplemental Resources.

2. *Identify laboratory procedure hazards*. Procedure hazards often found in a clinical lab include agent concentration, suspension volume, equipment and procedures that generate small-particle aerosols and larger airborne particles (droplets), complexity of lab procedures, and use of sharps.
3. *Make a final determination of the appropriate biosafety level and select additional precautions indicated by the risk assessment*. It is unlikely that a risk assessment would indicate a need to alter the recommended facility safeguards specified for the selected biosafety level. It is important to recognize that staff in the laboratory may differ in their susceptibility to disease. Consultation with an occupational physician knowledgeable in infectious disease is advised.
4. *Evaluate the proficiencies of staff regarding safe practices and the integrity of safety equipment*. An evaluation of the laboratorian's training, experience in handling infectious agents, proficiency in

the use of sterile techniques and BSC, ability to respond to emergencies, and willingness to accept responsibility for protecting one's self and others should be assessed.

5. *Review the risk assessment with a biosafety professional, subject matter expert, and the institutional biosafety committee*. Once the risk assessment is completed it should be reviewed by site-specific, and if necessary, local experts in biosafety. This review should include input from the IP, laboratory safety, and infection prevention and control committee, as well as safety committee.

As with any other risk assessment, specific gaps in biosafety should be identified and follow-up actions delineated to procure a safe environment. These actions should be regularly reviewed and updated as necessary.

LABORATORY BIOSECURITY

In response to the anthrax attacks on U.S. citizens in October 2001 and other events, laboratory specialists have recognized that there is a need to consider developing, implementing, and/or improving the security of biological agents and toxins capable of serious or fatal illness to humans. The term "biosecurity" refers to the protection of microbial agents from loss, theft, diversion, or international misuse. Labs should ensure that protective measures are provided and that the costs associated with protection are proportional to the risk. Biosecurity policies and procedures should not seek to protect against every conceivable risk.

For laboratories not handling select agents, the access controls and training requirements specified for BSL-2 and BSL-3 may provide sufficient security for the materials being studied.

A biosecurity risk assessment should be completed for each laboratory using these BMBL recommended steps:

- Identify and prioritize biological materials.
- Identify and prioritize the threat to biological materials.
- Analyze the risk of specific security scenarios.
- Design and develop an overall risk management program.
- Reevaluate the institution's risk posture and protection objectives.

LABORATORY RESPONSE NETWORK

In 1999, the CDC established the Laboratory Response Network (LRN). The purpose of the LRN is to run a network of laboratories that can respond to biologic and chemical terrorism. This multilevel system is designed to link frontline clinical microbiology laboratories, hospitals, and other institutions to state and local public health laboratories. These, in turn, will support advanced-capacity public health, military, veterinary, agricultural, water, and food testing laboratories at the federal level. LRN labs are designated as either national, reference, or sentinel. Designation depends on the types of tests a laboratory can perform and how it handles infectious agents to protect workers and the public. *National labs*have unique resources to handle highly infectious agents and the ability to identify specific agent strains. *Reference labs*, sometimes referred to as *confirmatory reference*, can perform tests to detect and confirm the presence of a threat agent. These labs ensure a timely local response in the event of a terrorist incident. Rather than having to rely on confirmation from labs at the CDC, reference labs are capable of producing conclusive results. This allows local authorities to respond quickly to emergencies. *Sentinel labs* represent the thousands of hospital-based labs that are on the front lines. Sentinel labs have direct contact with patients. In an unannounced or covert terrorist attack, patients provide specimens during routine patient care. Sentinel labs could be the first facility to spot a suspicious

specimen. Standard methods are available on the CDC Website as well as the Website of the American Society for Microbiology (ASM) (see Supplemental Resources). Sentinel labs are required to maintain awareness of bioterrorism agents and their identification. Laboratories should provide appropriate training, know who to call when an agent is suspected, and maintain the appropriate chain-of-custody requirements for specimens. Laboratorians should also be ready to transport specimens and refer testing as needed to the closest state public health laboratory or other approved reference facility.

WORK PRACTICES, SAFETY EQUIPMENT, AND FACILITY SAFEGUARDS

Clinical laboratories, especially those in healthcare facilities, receive clinical specimens with requests for a variety of diagnostic and clinical support services. Typically, the infectious nature of clinical material is unknown and specimens are often submitted with a broad request for microbiological examination for multiple agents (e.g., sputum submitted for "routine," acid-fast, and fungal cultures). Except in extraordinary circumstances, the initial processing of clinical specimens and serological identification of isolates can be done safely at BSL-2. Primary barriers such as BSC (Class I or II) should be used when performing procedures that might cause splashing, spraying, or splattering of droplets. BSCs should also be used for the initial processing of clinical specimens when the nature of the test requested or other information suggest the likely presence of an agent readily transmitted by infectious aerosol (e.g., *M. tuberculosis)*or when the use of a BSC (Class II) is indicated to protect the integrity of the specimen.

Most of the safe work practices expected in the laboratory as noted by the CDC's BMBL correlate with OSHA's Bloodborne Pathogen Standard and CDC's Standard Precautions. A listing of specific practices for each Biosafety level can be found in the BMBL.

The following standard and special practices, safety equipment, and facility requirements apply to the typical laboratory under BSL-2 criteria:

A. Standard Microbiological Practices

1. The laboratory supervisor must enforce the institutional policies that control access to the laboratory.
2. Persons must wash their hands after working with potentially hazardous materials and before leaving the laboratory.
3. Eating, drinking, smoking, handling contact lenses, applying cosmetics, and storing food for human consumption must not be permitted in laboratory areas. Food must be stored outside the laboratory area in cabinets or refrigerators designated and used for this purpose.
4. Mouth pipetting is prohibited; mechanical pipetting devices must be used.
5. Policies for the safe handling of sharps (e.g., needles, scalpels, pipettes, broken glassware) must be developed and implemented. Whenever practical, laboratory supervisors should adopt improved engineering and work practice controls that reduce risk of sharps injuries. Precautions, including those listed in the following, must always be taken with sharp items. These include:
    a. Needles must not be bent, sheared, broken, recapped, removed from disposable syringes, or otherwise manipulated by hand before disposal.
    b. Used disposable needles and syringes must be carefully placed in conveniently located puncture-resistant containers used for sharps disposal.
    c. Nondisposable sharps must be placed in a hard-walled container for transport to a processing area for decontamination, preferably by autoclaving.
    d. Broken glassware must not be handled directly. Instead, it must be removed using a brush and dustpan, tongs, or forceps. Plasticware should be substituted for glassware whenever possible.

6. Perform all procedures to minimize the creation of splashes and/or aerosols.
7. Decontaminate work surfaces after completion of work and after any spill or splash of potentially infectious material with appropriate disinfectant.
8. Decontaminate all cultures, stocks, and other potentially infectious materials before disposal using an effective method. Depending on where the decontamination will be performed, the following methods should be used prior to transport:
    a. Materials to be decontaminated outside of the immediate laboratory must be placed in a durable, leakproof container and secured for transport.
    b. Materials to be removed from the facility for decontamination must be packed in accordance with applicable local, state, and federal regulations.
9. A sign incorporating the universal biohazard symbol must be posted at the entrance to the laboratory when infectious agents are present. Posted information must include the laboratory's biosafety level, the supervisor's name (or other responsible personnel), telephone number, and required procedures for entering and exiting the laboratory. Agent information should be posted in accordance with the institutional policy.
10. An effective integrated pest management program is required. See Appendix G in the BMBL.
11. The laboratory supervisor must ensure that laboratory personnel receive appropriate training regarding their duties, the necessary precautions to prevent exposures, and exposure evaluation procedures. Personnel must receive annual updates or additional training when procedural or policy changes occur. Personal health status may affect an individual's susceptibility to infection and ability to receive immunizations or prophylactic interventions. Therefore, all laboratory personnel and particularly women of childbearing age should be provided with information regarding immune competence and conditions that may predispose them to infection. Individuals having these conditions should be encouraged to self-identify to the institution's healthcare provider for appropriate counseling and guidance.

B. Special Practices

1. All persons entering the laboratory must be advised of the potential hazards and meet specific entry/exit requirements.
2. Laboratory personnel must be provided medical surveillance and offered appropriate immunizations for agents handled or potentially present in the laboratory.
3. When appropriate, a baseline serum sample should be stored.
4. A laboratory-specific biosafety manual must be prepared and adopted as policy. The biosafety manual must be available and accessible.
5. The laboratory supervisor must ensure that laboratory personnel demonstrate proficiency in standard and special microbiological practices before working with BSL-2 agents.
6. Potentially infectious materials must be placed in a durable leakproof container during collection, handling, processing, storage, or transport within a facility.
7. Laboratory equipment should be decontaminated routinely, as well as after spills, splashes, or other potential contamination.
    a. Spills involving infectious materials must be contained, decontaminated, and cleaned up by staff properly trained and equipped to work with infectious material.
    b. Equipment must be decontaminated before repair, maintenance, or removal from the laboratory.
8. Incidents that may result in exposure to infectious materials must be immediately evaluated and treated according to procedures described in the laboratory biosafety safety manual. All such incidents must be reported to the laboratory supervisor. Medical evaluation, surveillance, and treatment should be provided and appropriate records maintained.

9. Animals and plants not associated with the work being performed must not be permitted in the laboratory.
10. All procedures involving the manipulation of infectious materials that may generate an aerosol should be conducted within a BSC or other physical containment devices.

C. Safety Equipment (Primary Barriers and Personal Protective Equipment)

1. Properly maintained BSCs (preferably Class II), other appropriate personal protective equipment, or other physical containment devices must be used whenever:
    a. Procedures with a potential for creating infectious aerosols or splashes are conducted. These may include pipetting, centrifuging, grinding, blending, shaking, mixing, sonicating, opening containers of infectious materials, inoculating animals intranasally, and harvesting infected tissues from animals or eggs.
    b. High concentrations or large volumes of infectious agents are used. Such materials may be centrifuged in the open laboratory using sealed rotor heads or centrifuge safety cups.
2. Protective laboratory coats, gowns, smocks, or uniforms designated for laboratory use must be worn while working with hazardous materials. Remove protective clothing before leaving for nonlaboratory areas (e.g., cafeteria, library, administrative offices). Dispose of protective clothing appropriately or deposit it for laundering by the institution. It is recommended that laboratory clothing not be taken home.
3. Eye and face protection (goggles, mask, face shield, or other splatter guard) is used for anticipated splashes or sprays of infectious or other hazardous materials when microorganisms must be handled outside the BSC or containment device. Eye and face protection must be disposed of with other contaminated laboratory waste or decontaminated before reuse. Persons who wear contact lenses in laboratories should also wear eye protection.
4. Gloves must be worn to protect hands from exposure to hazardous materials. Glove selection should be based on an appropriate risk assessment. Alternatives to latex gloves should be available. Gloves must not be worn outside the laboratory. In addition, BSL-2 laboratory workers should:
    a. Change gloves when contaminated, integrity has been compromised, or when otherwise necessary. Wear two pairs of gloves when appropriate.
    b. Remove gloves and wash hands when work with hazardous materials has been completed and before leaving the laboratory.
    c. Do not wash or reuse disposable gloves. Dispose of used gloves with other contaminated laboratory waste. Hand-washing protocols must be rigorously followed.
5. Eye, face, and respiratory protection should be used in rooms containing infected animals as determined by the risk assessment.

D. Laboratory Facilities (Secondary Barriers)

1. Laboratory doors should be self-closing and have locks in accordance with institutional policies.
2. Laboratories must have a sink for hand washing. The sink may be manually, hands-free, or automatically operated. It should be located near the exit door.
3. The laboratory should be designed so that it can be easily cleaned and decontaminated. Carpets and rugs in laboratories are not permitted.
4. Laboratory furniture must be capable of supporting anticipated loads and uses. Spaces between benches, cabinets, and equipment should be accessible for cleaning.
    a. Benchtops must be impervious to water and resistant to heat, organic solvents, acids, alkalis, and other chemicals.

   b. Chairs used in laboratory work must be covered with a nonporous material that can be easily cleaned and decontaminated with appropriate disinfectant.
5. Laboratory windows that open to the exterior are not recommended. However, if a laboratory does have windows that open to the exterior, they must be fitted with screens.
6. BSCs must be installed so that fluctuations of the room air supply and exhaust do not interfere with proper operations. BSCs should be located away from doors, windows that can be opened, heavily traveled laboratory areas, and other possible airflow disruptions.
7. Vacuum lines should be protected with HEPA filters or their equivalent. Filters must be replaced as needed. Liquid disinfectant traps may be required.
8. An eyewash station must be readily available.
9. Clinical laboratories must maintain proper air handling according to the procedures they are performing. Typically, a clinical lab has negative airflow to the adjacent areas. Specialized areas such as rooms where polymerase chain reaction (PCR) may need positive air pressure to limit potential RNA contamination of the reagents. Facilities should consider mechanical ventilation systems that provide an inward flow of air without recirculation to spaces outside of the laboratory.
10. HEPA-filtered exhaust air from a Class II BSC can be safely recirculated back into the laboratory environment if the cabinet is tested and certified at least annually and operated according to manufacturer's recommendations. BSCs can also be connected to the laboratory exhaust system by either a thimble (canopy) connection or a direct (hard) connection. Provisions to assure proper safety cabinet performance and air system operation must be verified.
11. A method for decontaminating all laboratory wastes should be available in the facility (e.g., autoclave, chemical disinfection, incineration, or other validated decontamination method).

LABORATORY EQUIPMENT

Biological Safety Cabinets

Various laboratory procedures generate aerosol particles that may spread biohazardous materials to the work area and pose a risk of infection to the worker. BSCs are used to prevent the escape of aerosols or droplets and to protect lab samples from airborne contamination. They are specifically designed to protect the individual and the environment from biological agents and to protect specimens and other materials from biological contamination. These devices are distinct from horizontal or vertical laminar flow hoods, which should never be used for handling biohazardous, toxic, or sensitizing material. Chemical fume hoods also should not be used for biohazards in that they are solely designed to protect the individual from exposure to chemicals and noxious gases. These chemical fume hoods are not equipped with HEPA filters.

There are three general types of BSCs: Classes I, II, and III (Figures 108-1, 108-2, and 108-3).[24] All BSCs must be recertified annually by an independent professional.

There is one type of Class I BSC. This cabinet is similar to a chemical fume hood and has an inward airflow through the front opening. Exhaust air from the BSC is passed through a HEPA filter so that the equipment protects both the worker and the general public. However, the specimens and other materials are potentially subject to contamination.

Class I BSCs are not generally recommended for work that involves biohazardous material.

Class II BSCs are designed to protect the worker, the general public, and the specimen. Airflow velocity at the face of the work opening is at least 75 linear ft/min (lfpm). Both the supply air and the exhaust air are HEPA-filtered. There are four types of Class II BSCs (IIA, IIB1, IIB2, and IIB3). They differ in the

amount of recirculation, downflow, and inflow. Usually, all but IIA are considered satisfactory for biohazardous and toxic agents.

Class III BSCs are totally enclosed, ventilated cabinets of gas-tight construction that offer the highest degree of protection from infectious aerosols. They also protect research materials from biological contamination. Class III BSCs are most suitable for work with hazardous agents that require containment at BL-3 or BL-4. All operations in the work area of the cabinet are performed through attached rubber gloves. The cabinets are operated under negative pressure. Supply air is HEPA-filtered, and the cabinet exhaust air is filtered by two HEPA filters in series or HEPA filtration followed by incineration before discharge outside of the facility. All equipment required by the laboratory activity, such as incubators, refrigerators, and centrifuges, must be an integral part of the cabinet system. The Class III BSC must be connected to double-door autoclaves and chemical dunk tanks to permit sterilization or disinfection of all materials before leaving the cabinet and also to allow supplies to enter the cabinet. Several Class III BSCs are therefore typically set up together as an interconnected system.

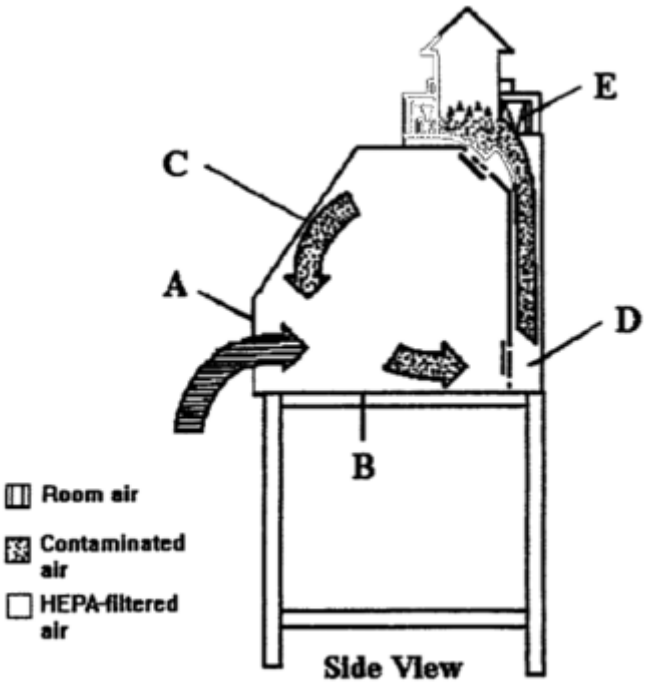

Figure 108-1.

Class I biological safety cabinets View Image

Some cabinets contain ultraviolet sterilizers. When required, blowers should be turned on for proper circulation before and after each procedure. Flow alarm systems should be checked each time they are used and should always be readily accessible. Interior surfaces should be decontaminated after each use.

Centrifuges

Centrifuges are commonly used in the clinical laboratory as part of specimen processing. Hazards associated with centrifuging include mechanical failure (e.g., rotor failure, tube or bucket failure) and the creation of aerosols. Aerosols are created by practices such as filling centrifuge tubes, removing plugs or caps from tubes after centrifugation, removing supernatant, suspending sediment pellets, and by the very process of centrifugation itself. The greatest aerosol hazard is created when a tube breaks during centrifugation. Special safety precautions can be used to decrease the risks associated with centrifugation. Examples of these precautions include using sealed tubes and safety buckets that seal with O-rings; filling open centrifuge tubes, rotors, and accessories in a BSC; and always balancing buckets, tubes, and rotors properly before centrifugation.

PHLEBOTOMY

In most hospital settings, the laboratory is responsible for most phlebotomy procedures. Given that it is almost impossible to identify what might be infectious without testing, all patients and their bodily fluids should be handled using Standard Precautions.[8,13,14,16] This is particularly true for a phlebotomist, who may be one of the first contacts a new patient has within a healthcare facility. OSHA's Bloodborne Pathogen Standard requires that gloves be worn when performing venipuncture. Other protective equipment such as goggles, mask, or lab coat may be required for a procedure based on the risk of

exposure (i.e., combative patient, arterial punctures). Safe needles, as defined by OSHA and other agencies, should be used whenever possible. Only single-use disposable tube holders should be used.[25]

All phlebotomy needles (even those defined as safe) and lancets should be disposed of promptly in a puncture-resistant container to prevent their reuse or accidental injury to a handler.

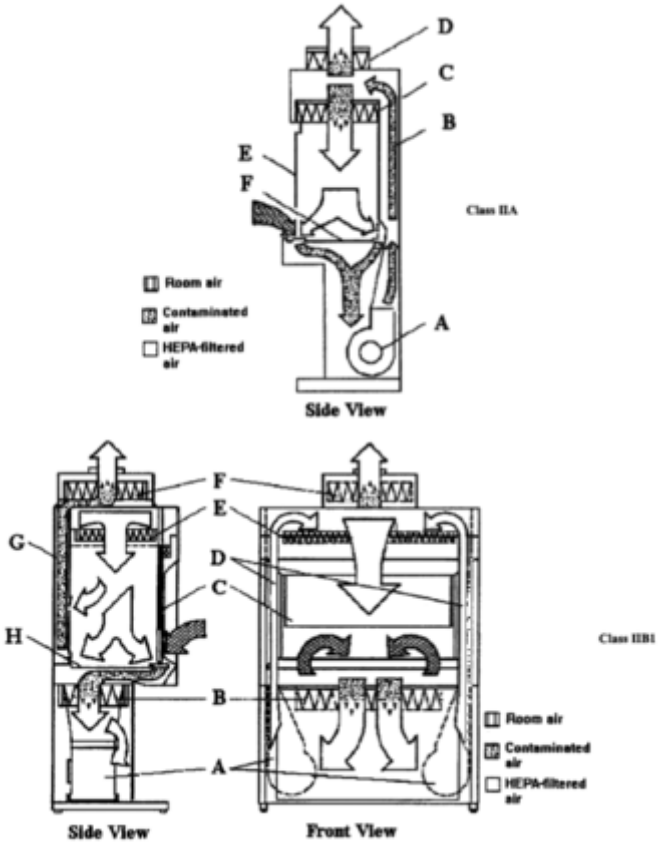

Figure 108-2. Class II biological **View Image**

Figure 108-3.

Class II biological safety cabinet **View Image**

Hand hygiene is the single most effective means of preventing transmission of infection. To protect the patient from colonization or infection after phlebotomy, the following measures should be employed: (1) tourniquets should be one-time use or one-patient use only; (2) skin should be antiseptically prepared before phlebotomy with either a 70 percent isopropyl alcohol prep or, in the case of blood cultures, 10 percent povidone iodine solution or chlorhexidine gluconate; and (3) a clean gauze pad, cotton ball, or bandage should be placed over the puncture site to stop bleeding if necessary. To protect the phlebotomist from infection and reduce the risk of infection to others, isolation precautions should be followed closely. Additional procedures may be necessary to avoid contamination of equipment.

.

TRANSPORTING BIOHAZARDOUS MATERIALS

Laboratories often need to transport biohazardous materials offsite. This transport may be across campus, across town to another laboratory, or across the country to a reference or research laboratory. Personnel who package and ship these specimens must be concerned with their safety and the protection and safety of those who receive the material. They must abide by the complex set of regulations that have been implemented to protect all handlers.[18,26,27,28,29]Inasmuch as these regulations are constantly being reviewed and updated, it is recommended that personnel check with each organization on a regular basis for any changes or updates.

Samples transported by local carriers such as cabs, hospital and clinical vehicles, or personal cars must meet packaging standards. In general, the requirements for shipping biohazard materials interstate or intrastate depend on the type and volume of specimen. The regulations define three types of specimens: biological products, diagnostic (clinical) substances, and infectious (etiological) substances. The respective shipping containers are similar but documentation is different.

Biologic products are finished biological substances for veterinary or human use such as vaccines and reagents. These products must meet public health standards (9 CFR Parts 102–104 and 21 CFR Parts 312 and 600–680). Diagnostic (clinical) material comprises excreta, secretions, blood and its components, as well as tissue and tissue fluids that are being shipped for diagnostic purposes. Infectious substances (etiological) include organisms known to be pathogenic to humans and clinical samples with a high likelihood of being infectious. Infectious substances could include clinical specimens such as an enzyme immunoassay (EIA), HIV-positive serum submitted for Western blot analysis, and sputum samples from patients known to be culture-positive for tuberculosis.

The essential element for protection is the triple-containment packaging, which is required for shipping each of these substances. In all categories and volumes, there must be a primary container accompanied by enough absorbent material to contain the whole sample, a waterproof container, and an outer container. The packaging is expected to be able to withstand rough handling and passage through cancellation machines, sorters, and conveyers throughout transport. The sample identification document must be located outside the secondary containment. Additionally, labels clearly marking the biohazard level must be prominently displayed on the outside container. Depending on the level of biohazard, additional labels and information may need to be displayed as well.

INFECTIOUS WASTE MANAGEMENT

As one of the principal generators of infectious hazardous waste in healthcare facilities, the clinical laboratory is responsible for the proper handling and disposal of this waste. According to the Environmental Protection Agency's (EPA's) *Guide for Infectious Waste Management*,[7,9] laboratory infectious waste includes cultures and stocks of infectious agents and associated biological matter (includes disposable culture dishes and devices used to transfer, inoculate, and mix cultures), pathological wastes (includes wet tissues, organs, body parts, blood and body fluids removed during surgery, autopsy, and biopsies), human blood and blood products (includes waste blood, serum, plasma, and other blood components), contaminated sharps (including hypodermic needles, syringes, scalpel

blades, Pasteur pipettes, broken glass), and isolation wastes (includes blood, excretions, exudates, and secretions from patients with highly communicable diseases).

Many federal agencies have developed guidelines and regulations for handling these wastes. Of primary importance is the CLSI Document GP5—*Clinical Laboratory Waste Management*.[9]In general, waste from the laboratory can be handled just as any other infectious waste in facilities with some awareness of some essential issues that affect laboratories specifically. Also, the Department of Transportation's infectious waste should be segregated in the clinical lab from general laboratory waste and by treatment or disposal methods. Sharps should be placed into appropriate puncture-resistant containers. In most facilities, large quantities of liquid body fluid waste may be safely poured down the sink. Materials of high-water content or density (i.e., anatomical waste) should be incinerated, whereas microbiology laboratory waste may be autoclaved. To the extent feasible, segregation and subsequent treatment should minimize handling and transportation from the generation site to the decontamination mechanism. Containment requirements should be compatible with treatment mechanisms and should not hinder the decontamination process.

In the laboratory, there is a wide variety and a large amount of contaminated sharps. These sharps include phlebotomy needles, vial inoculation needles, scalpel blades, Pasteur pipettes, broken glass, coverslips, glass slides, and capillary tubes. Whenever possible, safer devices should be used to decrease risk of exposure (e.g., cannulas or plastic-tipped pipettes should be used instead of needles or fragile glass or plastic pipettes).

Large quantities of liquid body fluid waste must be disposed of in the laboratory. These include 24-hour urine specimens and vacuumed tubes of blood. If local health codes permit, blood and body fluids may be disposed of by pouring them down a sink into the sanitary sewer. Extreme caution to prevent splashing must be exercised in such disposal of fluids. Water should not be running in the sink while blood or bodily fluids are decanted. Decanting should be followed with copious amounts of water. If there is any risk of splattering, the laboratorian should wear facial protection and a fluidproof apron in addition to the gloves and lab coat. Sinks used for biohazardous waste disposal should not be used for hand washing.

Microbiological cultures should not be discarded directly into sanitary sewers or landfills. These wastes should be autoclaved prior to leaving the facility or incinerated before final disposal either by the laboratory or the biological waste vendor. Most clinical laboratories currently contract incineration to a licensed vendor rather than contend with local and state regulations associated with incinerators. However, laboratories, particularly those involved in anatomical work, may decontaminate and render unrecognizable anatomical wastes by a gravity displacement or prevacuum autoclave.

Steam autoclaves are the method of choice for decontaminating discarded cultures of CDC's select agents and for any material that may be contaminated with these organisms. Examples of these organisms include *Brucella*spp., *Francisella tularensis,* rickettsial agents, and rabies virus. Clinical laboratories are no longer allowed to maintain stock cultures of CDC's select agents.

There is no standard method for autoclaving and monitoring. Time and temperature criteria determined by the manufacturers of the equipment vary with processing times and are usually between 60 and 90 minutes or more at 120°C. Manufacturers' recommended protocols for use and maintenance should be followed. All autoclaves must be checked at least weekly for proper function using a biological indicator (e.g., *Bacillus stearothermophilus* spores) or its chemical equivalent. The Association for the

Advancement of Medical Instrumentation has developed a recommended protocol to use with this monitor.[9]

If laboratory wastes must be stored before disposal, storage should be as brief as possible. The site must be properly identified with a biohazard label, have restricted access, and be located near the site of generation. Long-term storage for waste awaiting offsite disposal should be located near the treatment site or loading dock, have limited access, and meet EPA requirements. The area should be thoroughly cleaned each time it is emptied of waste contents. Direct sewer connections with proper grading from this area are also recommended.

OCCUPATIONAL PREVENTION AND EXPOSURES

From the infection prevention perspective, the goal of occupational health in a clinical lab and in university research laboratories is to promote a safe and healthy workplace. Prospective workers should be educated about the biohazards to which they may be occupationally exposed, the types of exposures that place their health at risk, the nature and significance of such risks, and the appropriate first aid and follow-up for potential exposures. That information should be reinforced annually, at the time of any significant change in job responsibility, and following recognized and suspected exposures.

Workers who may be exposed to highly pathogenic agents—such as in a clinical research lab—should receive a preplacement medical evaluation. Healthcare providers should be cognizant of potential hazards encountered by the worker. A description of the requirements for the position and an understanding of the potential health hazards present in the work environment, provided by the worker's supervisor, should guide the evaluation. The healthcare provider should review the worker's previous and ongoing medical problems, current medications, allergies to medicines, animals, and other environmental proteins, and prior immunizations. With that information, the healthcare provider determines what medical services are indicated to permit the individual to safely assume the duties of the position. Comprehensive physical examinations are rarely indicated. In a research laboratory setting when occupational exposure to human pathogens is a risk, employers should consider collecting and storing a serum specimen prior to the initiation of work with the agent. This is not typically necessary in a clinical laboratory but should be considered for research laboratories in a university setting. It can be used to establish baseline seroreactivity. This will be important should additional blood samples need to be collected for serological testing subsequent to a recognized or suspected exposure.

Commercial vaccines should be made available to workers to provide protection against infectious agents to which they may be occupationally exposed. Investigational vaccines for eastern equine encephalomyelitis virus, Venezuelan equine encephalitis virus, western equine encephalomyelitis virus, and Rift Valley fever viruses may be necessary in some laboratories

Routine, periodic medical evaluations generally are not recommended; however, limited periodic medical evaluations or medical clearances targeted to job requirements may occasionally be warranted (e.g., respirator usage).[3]In special circumstances, it may be appropriate to offer periodic laboratory testing to workers with substantial risk of exposure to infectious agents to detect preclinical or subclinical evidence for an occupationally acquired infection.

Workers should be encouraged to seek medical evaluation for symptoms that they suspect may be related to infectious agents in their work area without fear of reprisal. A high index of suspicion for potential occupational exposures should be maintained during any unexplained illness among workers or visitors to worksites containing biohazards. Modes of transmission, as well as the clinical presentation of infections acquired through occupational exposures, may differ markedly from naturally acquired

infections. Fatal occupational infections have resulted from apparently trivial exposures. A close working relationship with the research or clinical program in which the affected employee works is absolutely essential. In the event of injury, consultation between healthcare provider, employee, and the employee's supervisor is required for proper medical management and recordkeeping.

All occupational injuries must be reported to the occupational health department. Laboratory standard operating procedures should include a printed summary of the recommended medical response to specific exposures that can guide immediate response in the workplace and that the injured worker can provide to the treating facility. The medical provider's description of the injury should include:

- The potential infectious agent
- The mechanism and route of exposure (percutaneous, splash to mucous membranes or skin, aerosol, etc.)
- Time and place of the incident
- Personal protective equipment used at the time of the injury
- Prior first aid provided (e.g., nature and duration of cleaning and other aid, time that lapsed from exposure to treatment)
- Aspects of the worker's personal medical history relevant to risk of infection or complications of treatment
- Department supervisor(s), witness (if applicable)

Postexposure serologic testing may be useful, but it is important to determine how information obtained from serologic testing will be interpreted. It is also essential to collect serum specimens at the appropriate interval for a given situation. Assessment of seroreactivity in exposed workers is most helpful when the results of specimens collected over time can be compared. Ideally, specimens collected prior to, at the time of, and several weeks following exposure should be tested simultaneously and results compared to assess changes in the pattern of seroreactivity. Serum collected too early after exposure may fail to react even when infection has occurred, because antibodies have not yet been produced in detectable quantities. When immediate institution of postexposure prophylaxis may delay seroconversion, or when the agent to which the worker was exposed results in seroconversion, testing of specimens collected late after exposure is particularly important.

Testing of a single serum specimen is generally discouraged and can result in misinterpretation of nonspecific seroreactivity. Evidence of seroconversion or a significant (fourfold) increase in titer associated with a compatible clinical syndrome is highly suggestive of acute infection.

Conclusions

The laboratory plays an integral role in the clinical setting by providing valuable information to clinicians. Because of its specialized setting, the laboratory and laboratory workers may be at increased risk of contamination/infection. Regulations and recommendations exist to ensure the safety of the laboratory environment and those that work in them.

Future Trends

As healthcare resources become more limited, there has been increasing use of reference laboratories. This has signaled a shift from hospital-based laboratories to a more regional approach. In many areas, individual hospitals provide only a small number of laboratory tests on-site. Nonemergent or routine tests are sent to a regional or reference laboratory that supports surrounding healthcare facilities. When changes like this are being considered, it is important to recognize the impact on clinical diagnosis and other ancillary services. For example, if microbiological tests are not conducted in house, will a representative from the referring laboratory be available to sit on the processing laboratory's infection prevention committee?

More and more IPs are working in collaboration with industrial hygienists in maintaining a safe environment in the research and clinical laboratories in large university settings, as well as in research labs in manufacturing and pharmaceutical settings. Concerns of transmission prevention as well as symptom recognitions has stimulated this interesting new area for IPs.

International Perspective

Given the ease of travel between countries, the world is becoming smaller. Laboratories around the world need to be aware of biologic agents that were once thought to be isolated to specific geographic areas. Additionally, as the global healthcare system grows and changes, we need to recognize that there are no universal laboratory safety regulations.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Nutrition Services

Author(s): Ruby Puckett, MA, FCSI
President of Foodservice Management Consultants

Program Director for Dietary Manager Training
University of Florida
Gainesville, FL

Published: October 3, 2014

Abstract

The goal of this chapter is to identify the responsibilities of the food and nutrition services department for infection prevention and to provide methodologies for preventing foodborne illness. This chapter provides insight into the practices and interventions used to prevent foodborne-associated infections and outbreaks. Food Code 2009 and 2013 provide guidance on food safety, sanitation, and other related requirements to protect the food that is prepared and served. Food Code 2009 is still applicable but added supplement to this code is now Food Code 2013. Changes are incorporated in this chapter. Written policies and procedures provide standards for safety and sanitary handling of food and cleaning and maintenance of food service equipment, cleaning supplies, and personnel. The department must also be knowledgeable with the activities that may influence the infection risk of patients, employees, and their customers. Procedures are developed in case of an outbreak. The Hazard Analysis and Critical Control Point guidelines, a national standard for providing safety precautions in food service and assuring safe practices, need to be implemented to verify that the system is working. A disaster preparedness program for the safety of food and water is coordinated with the overall facility plan.

Key Concepts

- Food and nutrition services provide safe food and beverages and have responsibilities involving prevention strategies.
- Food should be purchased from approved sources that meet the standards developed by regulatory agencies.
- Clean, properly equipped, temperature-controlled storage and working areas must be provided.
- Calibrated measuring instruments should be used to monitor temperatures.

- Food should be received and stored under conditions that maintain nutritional value and minimize the risk of contamination by microorganisms, insects, rodents, and toxic substances.
- Policies and procedures for maintaining staff hygiene, preparing and serving food on a daily basis, separating clean and dirty, and cleaning and sanitizing equipment, utensils, and work areas should be developed.
- Records of food and equipment temperatures must be maintained, and remediation steps when systems are not in control must be developed. Frequent self-inspections should be conducted, and immediate action taken to correct any problem.
- Waste materials should be disposed according to accepted sanitation principles as well as federal and local health department regulations.
- Training programs and employee supervision should be conducted to ensure adherence to approved policies and procedures.
- Schedules should be developed for cleaning, sanitizing, and disinfecting the department and should include use of appropriate agents and, if required, instructions on the use of personal protective equipment.
- Procedures for monitoring time, temperature, and cross-contamination, and also for initiating the hazard analysis critical control principles practices, should be established.
- Correct techniques in handling ice and products in modified atmosphere packing, and also in ultrahigh temperature processing, should be used.
- Policies and procedures should be developed for providing safe food in vending machines.
- Policies and procedures should be developed for collaboration, communication, and participation with infection prevention and public health officials during each step of an investigation of a foodborne outbreak.
- Food and nutrition services should participate on the facility Infection Control Committee.1

Background

This chapter provides information to assist the infection preventionist (IP) in understanding the food and nutrition services (FNS) department and its unique role in healthcare—providing safe food and beverages to patients, employees, and customers—and its role in reducing the risk of foodborne illness.

FNS is an important component of infection prevention in healthcare facilities. The routine operation of FNS provides nutritious, safe food and beverages for patients, visitors, and healthcare personnel (HCP). During national recalls or local food contamination incidents, the FNS leadership and the IP work together to implement strategies to ensure a safe food supply chain. Appropriate management and control of the delivery of food from the farm to the table is the foundation of safe products. FNS policies and practices follow accepted food management standards as outlined by local, state, federal, and surveying agencies. The Hazard Analysis and Critical Control Point (HACCP) guidelines and other standards related to production, receiving, storage, serving, disaster preparedness, and waste management help to ensure a safe food chain.[1]Adherence to these recommended practices prevents system failures that can lead to foodborne illness. Although breaches in accepted practice may contribute to foodborne illness, there have been multiple outbreaks reported that have been related to food supply chain contamination. The IP, the food service management team, and public health officials must establish open and ongoing communication and work together to identify practices and sources of foodborne illness.

Infection Risk

When all personnel work together to provide sanitary and safe care; safe, nutritious food; and medical nutrition therapy, the clientele is best served. When necessary, this also includes investigation of potential foodborne illness. Safe food practice begins with purchasing from approved reputable suppliers and establishing safe storage practices. It also includes holding and serving the food appropriately. The FNS must develop standards for the evaluation of the food served to all customers. Two important standards are time and temperature of the food served and employee hygiene.[1]

FNS leadership must monitor performance against standards for outcomes, record infractions and corrective action taken, and make standard changes, as appropriate, when the standards are poorly designed.

The assistance of state and local health authorities can help enhance the healthcare facility's food safety program and ensure that the food provided to patients, residents, and visitors will be free from infection risk.

FNS has the responsibility to ensure that the facility serves foods and beverages that are safe and free from contamination. Statistics from 2011 show that the major contributing factors for foodborne illness were improper hand washing and bare-hand food contact by a food service employee.[2]Other causes for foodborne illness were the following:

- Improper temperature in storage (dry, refrigerated, freezer and defrosting), production hot-holding, improper cooling, and reheating[3,4]
- Infected person handling food[5]
- Cross-contamination (contaminated prepared food and raw ingredients, contaminated food preparation work area, utensils, and other equipment)[1,6]
- Improper cleaning/sanitizing of utensils, trays, dishes, glasses, equipment, and work areas[6]
- Food from unsafe source, poor utilization of leftovers, adding of unsafe chemicals[1,2]
- Pathogens naturally present in food supply
- Contamination or mishandling during processing, transport, storage, preparation, and/or serving
- Pathogens may grow, when new pathogens are introduced, and other biological, chemical, and physical contaminations may enter food[6]

Hazardous Agents

There have been reported outbreaks of foodborne illness in all areas in the food chain, which affected patients/residents, as well as HCP and visitors. According to the latest information from the Centers for Disease Control and Prevention (CDC), it is estimated that one in six Americans (or 48 million people) get sick, 128,000 are hospitalized, and 3,000 die from foodborne illness annually.[7]*Salmonella*has been reported as the major cause of illness.[8]There are 250 known foodborne illnesses caused by bacteria, viruses, and parasites. Young children and older adults were most likely to have severe complications or die from these illnesses. Thirteen percent of infections, 24 percent of hospitalizations, and 57 percent of deaths occurred among adults age 65 years or older. *Salmonella*was the most common infection (1.2

million U.S. illnesses annually) and the most common cause of hospitalization and death that was tracked.[8]

The yearly cost of all foodborne illness is approximately $5 to $6 billion in direct medical expense and loss of productivity. The CDC has estimated that for two major groups of foodborne illness there are 31 known pathogens, including[8]:

- Norovirus (5,461,731 illnesses, 14,663 hospitalizations, 149 deaths)
- *Salmonella*nontyphoidal (1,027,561 illnesses, 19,336 hospitalizations, 378 death—highest incidence of death)
- *Clostridium perfringens*(965,958 illnesses; no information available for hospitalization and deaths)
- *Campylobacter*spp. (845,024 hospitalizations, 76 deaths)
- *Staphylococcus aureus*(241,148 illnesses)
- *Toxoplasma gondii*(4,428 hospitalizations, 327 deaths)
- Shiga toxin-producing *Escherichiacoli*(STEC) O157 (2,138 hospitalizations)
- *Listeria monocytogenes*(255 deaths)[7,8]

Laboratory-confirmed infections with *Campylobacter, Cryptosporidium, Salmonella, E. coli*(O157 and non-O157), *Shigella,*and *Yersinia*were the highest among children under 5 years of age. The incidences of *Cyclospora, Listeria,*and *Vibro*infections were the highest among adults 65 years and older.

*V. vulnificus*is found in raw, improperly cooked, or cooked recontaminated fish, shellfish, or crustaceans, especially oysters harvested along the Gulf of Mexico coast from April to October, when the bacteria thrives in the warm Gulf Coast waters. The Florida Administrative Code states that establishments serving raw oysters are required to display "either on the menu, tabletop, or elsewhere in *plain view of all patrons,*the following notice: There is a risk associated with consuming raw oysters. . .If unsure of your risk, consult a physician."[1]

Foodborne illness can be caused by a variety of organisms. These include bacteria, viruses, parasites, fungi, and helminths (wormlike parasites, hookworms, whipworms, and flukes).[9,10,11]Illness is caused by ingesting food that contains a pathogenic agent. Common signs and symptoms of illness can range from upset stomach, diarrhea, fever, vomiting, abdominal cramps, and dehydration to a more severe illness and even death.[1,6,10,11]If symptoms are severe or persist, medical help should be sought. This is especially true for pregnant women, newborns, young children, older adults, and people with weakened immune systems.[1,6,10]The local health department should be notified of the foodborne illness.[1,6,10]

*Bacterial agents*produce foodborne infection after ingestion of a contaminated food product and replication in a susceptible host. They include *Salmonella*spp., *Clostridium botulinum, Clostridium perfringens, Bacillus subtilis, B. cereus, E. coli, Shigella*spp., *Vibrio parahaemolyticus, Streptococcus pyogenes*group A, *Campylobacter*spp., and *Listeria monocytogenes*.[1,10,11]

Food sources for bacteria include protein foods such as milk, raw meat, poultry, shellfish, raw milk, processed meat, soft cheese, ground meat, ham, cold cuts, and fish. Other foods include cereal, rice, starchy foods, cream-filled desserts, raw seed sprouts, and large quantities of food held at room temperature or cooled too slowly, and contaminated water. There have also been outbreaks of ingested

strawberries, raspberries, cantaloupe, chopped salad mixes, garlic in oil, peanut butter, and Greek yogurt resulting from improper food handling.[1,10,11,12]

*Viruses*require living cells to replicate, so—unlike bacteria—they will not replicate in food. Once a virus enters a living cell, it interrupts the cell's life process and uses the cell to produce more viruses. The major source of viral foodborne illness includes contaminated water, iced drinks, water, salads and ready-to-eat foods, food handled by infected employees who failed to follow correct personal hygiene practices, and, if eaten raw, molluscan shellfish (oysters, mussels, and clams harvested from polluted water). Shellfish should be purchased only from a certified source. Potable water is to be used for washing produce, drinking, making cold beverages (noncarbonated), for all preparation of food, and for cleaning. Viruses include Hepatitis A, Hepatitis E, and norovirus.[1,10,11]

*Parasities*are organisms that must live in or on a specific host to survive. They do not grow on food. The parasite is transmitted from animals to humans if food is not cooked thoroughly. Parasites are naturally present in many animals such as pigs, cats, rodents, and fish. Pork and fish must be cooked to proper temperature or a foodborne illness caused by parasites could result. Parasites include *Toxoplasma gondii, Entamoeba histolytica, Cryptosporidium parvum,*and *Cyclospora*.[1,10,11]See other chapters in the APIC Text that address these pathogens.

Agents that replicate in food and produce foodborne intoxication when ingested by the host include *Staphylococcus aureus, Bacillus cereus, C. botulinum, Clostridium perfringens, Vibrio cholerae, Shigella*spp., *E. coli,Giardia lamblia, Cryptosporidium parvum,Cyclospora, Trichinella spiralis*(a roundworm found in pork and wild game), and *Anisakis*(a roundworm found in fish). Foods in which they may be found must be cooked thoroughly to destroy potential parasites.[1,6,11]

There are *natural toxins*found in some food sources. They include two fish toxins (scrombroid and ciguatera), shellfish toxins, and mushrooms. Plant food toxins can be found in honey from bees that gathered nectar from mountain laurel and rhododendrons, apricot, kernels, fava beans, Jimson weed, rhubarb, and in milk from cows that have eaten snakeroot, crocus seeds, raw cassava, sunburned green potato skins, raw castor beans, hemlock flowers, and leaves.[1,13]

Monitoring for Contamination

A cluster of similar illnesses that might be attributable to healthcare-prepared food in those who ate at the facility should raise the suspicion of foodborne illness. When such an outbreak is suspected, an investigation that includes epidemiological assessment and appropriate microbiologic monitoring is to be considered. Routine microbiologic sampling of food is not recommended and should be discouraged. Hospital-prepared infant and adult enteral formulas may need to be tested. When the diagnosis of a foodborne illness is verified, food service personnel are to notify their supervisor. Coordination with local public health officials is mandatory in many states. Together the FNS manager, the IP, and public health official should determine which food items are suspect. Samples from the same lot or batch should be saved. When appropriate, food items should be cultured. Comparison samples are not desirable. The actual food from the same batch or lot should be cultured. Routine culturing of food service personnel is not recommended but may be required by some local agencies.[1,6,7,13]

Addressing a Foodborne Outbreak

During a foodborne outbreak, the FNS department should:

- Save suspected foods for culturing by an appropriate laboratory.
- Document departmental conditions at the time of preparation of suspected food.
- Report gastrointestinal symptoms from patients, visitors, or HCP to the IP/employee/occupational health.
- Provide a list of foods served during the suspected interval.
- Implement and supervise control measures to prevent further occurrence of the illness.
- Follow state and local laws/regulations when reporting to local health authorities.[1,13]

Investigating a Foodborne Outbreak

According to the CDC website for foodborne disease, "a foodborne-disease outbreak (FBDO) is defined as an incident in which two or more persons experience a similar illness resulting from the ingestion of a common food."[7]Proving the linkage of the disease to the food requires collecting an optimal specimen for laboratory confirmation.

The CDC has sample questionnaires to assist the IP and FNS manager in collecting data during an outbreak investigation. Details on how to investigate a foodborne illness can also be found in *Foodservice Manual for Health Care Institutions,*4th ed., Chapter 13, pages 267–276.[1]

The following steps are used in an investigation.

1. Establish that an outbreak exists, as opposed to a pseudoepidemic or endemic case.
2. Develop case definitions.
3. Verify the diagnosis by appropriate clinical and laboratory tests.
4. Notify appropriate public health authorities.
5. Search for new or additional cases.
6. Characterize the cases in terms of time and place.
    a. Interview those who were sick and those who were not (cases and non-cases) for date of onset, meals/foods eaten (minimally 3 days before onset), and other activities related to the onset.
    b. Calculate food-specific attack rates.
7. Culture implicated food if available (usually not applicable to a standard healthcare facility laboratory).
8. Formulate a hypothesis.
9. Initiate control measures.
10. Prepare and distribute a final report to appropriate personnel, documenting the epidemiological features of the outbreak, mode of transmission of the infectious agent, and control measures implemented.

Please also refer to **12. Outbreak Investigations**and **83. Foodborne Illnesses**.

Surveying Agencies for Healthcare FNS

A healthcare department may be surveyed by The Joint Commission (TJC), the Centers for Medicare & Medicaid Services (CMS), state licensing agencies, the county health department, and the Occupational Safety and Health Administration (OSHA). Surveys are conducted against standards developed by Congress, state legislatures, and by state, county, and municipal agencies. The purpose of the surveys is to protect the health of the public by preventing or correcting unhealthy sanitation practices. Most of the agencies conduct on-site inspections, which may be unannounced. All of the agencies listed have

standards/requirements that relate to FNS. The surveyors may ask the FNS director to provide documentation and information pertinent to the survey. Most of the states have adopted U.S. Department of Agriculture (USDA)/Food and Drug Administration (FDA) food code standards. The FNS department should have copies of all applicable standards. It is the responsibility of the FNS director to educate the staff on standards used by the surveyor. Employees need to participate in mock surveys to understand the process used by the surveyors.[1'6]

Environmental Concerns

Plumbing systems are of particular environmental concern for infection prevention in the FNS department. Plumbing systems perform two very important functions: bringing potable water to the operation and removing waste to the sewer system or disposal plant. Plumbing is inspected as a part of the surveying process and local health inspection. The following items are included in a survey or inspection[1'6]:

1. The water supply must be protected from contamination by avoiding *cross-connections*or any physical link through which contaminants from drains, sewers, or waste pipes can enter a potable water supply.[1'5'6]
2. Plumbing fixtures such as hand-washing sinks, toilets, and urinals shall be cleaned as often as necessary to keep them clean.[5]Toilet tissue is provided in each toilet stall, covered waste receptacles are in each restroom, and hand-washing signs are posted in each toilet room used by employees.
3. All poisonous or toxic materials such as insecticides, detergents, disinfectants, or polishes should be clearly labeled and stored separately from food storage or preparation areas.[1'6]
4. Lighting, ventilation, and humidity controls are necessary to prevent the condensation of moisture and growth of molds.[1,6]
5. Heating/ventilation/air condition systems are designed and installed so that air intake and exhaust vents do not cause contamination of food, contact surfaces, equipment, or utensils.[1'6]

Management of Waste and Pest Control

Accumulations of garbage attract and provide refuge for pests (e.g., rodents, roaches, and flies). Leakproof, easily cleaned, pestproof, nonabsorbent garbage containers with tight-fitting lids help to reduce pest infestation. Garbage in containers should be moved as soon as possible from the kitchen area to the facility garbage holding area.[1'6]

Contracts for waste disposal should establish an appropriate pickup and removal schedule to remove garbage and other waste. All containers (cans, compactors, and dumpsites) should be outdoors and on a smooth surface of nonabsorbent material (e.g., concrete and asphalt). These areas need to be separate from food equipment, utensils, and linens.[1'13'14]

Providing prompt waste removal and area cleanliness reduces the risk of insects and vermin at the outside pickup site. Infestations can quickly move into healthcare facilities. Container should be washed in an area with a floor drain connected to a sanitary sewer system.[1'5'15'16]

An integrated pest management (IPM) system uses a variety of techniques to prevent pest infestation. The main objectives of IPM are[1'5'6'13,14,15,16,17]:

- Ensuring that all openings are sealed (e.g., cracks, tears in screens, tight-fitting windows and doors)
- Keeping area in good repair
- Inspecting incoming deliveries for infestation
- Checking produce area for roaches
- Monitoring all dry products in storage area
- Keeping area clean and sanitized
- Hiring a licensed pest control employer/operator—a person trained and licensed in pest management and control—to inspect, identify, evaluate, and report reasons for pests in the facility and report sanitation issues or structural conditions conducive to pest infestation

Basic Principles

The FNS department is responsible for the development of purchasing specifications that meet standards of safety and sanitation for food, equipment, and cleaning supplies. The FNS department should maintain and clean work areas, storage areas, and equipment for the handling of supplies in accordance with state and local health department standards and HACCP guidelines. The department should have written standards for safe preparation, handling, and storage of food to minimize contamination by microorganisms and chemicals.[1]There should be standards for cleaning and sanitizing hoods, grease trays, garbage disposal units, tray liners, and delivery carts.[1]The department needs to have written policies and procedures regarding employee health as outlined in the latest issue of the Food Code.[18]Employee health policies and procedures should be included in the department orientation and handbook, human resources, and employee health and facility infection prevention policies and procedures.[18]To prevent foodborne illnesses, written standards for cleaning and sanitizing trays, utensils, tableware, and other surfaces, and disposal of dietary waste, are essential. The department is required to comply with the local health department regulations for storage, handling, and disposal of garbage.

Educational programs on food preparation and personal hygiene should be conducted for HCP accompanied by monitoring and feedback of practice compliance.[1,5]Personal hygiene policies and practices are critical to ensuring that food service employees are healthy and provide safe food preparation. Foodborne illness related to *S. aureus*skin infections and *Salmonella*has been linked to infected food handlers. Poor personal hygiene by food handlers is the second most common practice associated with foodborne disease.[1]

Guidelines For Food And Nutrition Responsibilites

Purchasing

Purchasing is the first step in the movement of food from the supplier. The purchasing process includes:

- Selecting suppliers to the facility that offer quality products, delivered in safe and sanitary conditions
- Delivery of products in appropriate vehicles (refrigerated, enclosed vehicles)
- Securing products from an approved source. An approved source is one that is inspected based on federal, state, and local laws and has appropriate HACCP procedures in place[1,6,7,19]

- Securing products that have complete, verifiable specifications
- Containment of products in the appropriate packing or containers (avoid products in glass containers due to possible breakage)[1'6'7'18'20]

When food is purchased it may contain intrinsic contamination: microorganisms intrinsically may replicate, causing increased risk of producing food-related illness when ingested. Persons with a compromised immune system, children, pregnant women, and elderly persons are at particular risk from foods with intrinsic microbial contamination. For example, *Campylobacter*spp., *E. coli*, and *Salmonella*spp. have been associated with a variety of products, including beef, pork, poultry, eggs, and most recently peanut butter and its secondary products. Hepatitis A virus has been isolated from shellfish. *T. spiralis*has been isolated from pork; however, the incidence of related illness has declined in recent years. More recently, enterohemorrhagic *E. coli*O157:H7 has been associated primarily with undercooked beef. Contaminated fresh produce has caused bacteria, protozoan, and Hepatitis A outbreaks. *Listeria monocytogenes*has been found in ready-to-eat foods, including luncheon meats and soft cheeses. Imported natural cheeses can also be contaminated with *Listeria*. Persons with a compromised immune system, children, pregnant women, and elderly persons should avoid these foods and drink only pasteurized juice and cider.[1'6'11]

The purchase of eggs in shells should be limited. Outbreaks of *Salmonella enteritidis*have been traced to the use of clean, whole, uncracked-shell eggs. The FDA classifies whole-shell eggs as potentially hazardous food and recommends limiting the use of eggs in the shell. *Salmonella*infections are a concern in eggs. The intestine of most chickens may contain *Salmonella*. The bacteria from the intestinal tract may be passed on to the hands of the food service personnel and then on to food. Hand washing is vital when handling eggs. Eating raw eggs can be dangerous and is discouraged. The FNS department should use pasteurized eggs as much as possible, and eggs in shells should be limited to preparations requiring them (e.g., boiled, fried, poached and not runny, and catering situations). Potentially hazardous food also should be free of previous extreme alterations in temperature.[1'7'18]

Purchasing food from an approved source is paramount. The CMS recently updated and expanded guidelines regarding food safety in purchasing.[18]The new information states ". . . healthcare facilities the foodservice must purchase and prepare foods from an approved source only. Food from an *unapproved*source includes broad donations, or individual purchases of tomatoes, strawberries, or corn; as well as home-baked goods or home-canned goods from a farm market, roadside stand, or personal home."[20]Generally, food supplies are safe. Products selected should be in commercially filled unopened packages when possible. This would also include tube-feeding formula.[1'6'19,20,21,22,23]

Receiving

Foods received on the loading dock should be inspected immediately. Anything in a damaged container should be rejected. Delivery trucks should be inspected for cleanliness and temperature controls appropriate for fresh and frozen products. A schedule for delivery needs to be followed.

The receiving personnel should check the following items:

- Temperature strips of potentially hazardous foods[1]
- Inspection stamps and labels/tags of meats, eggs, milk, poultry, fish, juice, and pureed foods (eggs should have a grade seal of Grade A or Grade AA and should be clean and have uncracked shells)[7]

- All use-by and expiration dates[1,6,10,23,24,25]
- Color, texture, odor, and condition of products[1,6,19,23,24,25]
- Temperature of frozen and refrigerated food, including milk. When the outside temperature reaches 90°F, all refrigerated perishable item need to be refrigerated within *1*hour.[10,26,27,28]
- Thawed, dripping, and refrozen products[1]
- Open and examine contents of tampered or damaged containers; if appropriate reject product.[1,26,28]
- Inspect for signs of pest infestation and/or spoilage.[1,6,10,23,25]

Storage of Food

Improper storage or poor environmental sanitation may introduce contamination or allow bacteria in the food to increase. To meet food safety requirements, food storage follows a systematic method called FIFO (first in, first out). Food should be protected from cross-contamination by separating raw animal foods during storage, preparation, holding, and display from raw ready-to-eat food, including fruits and vegetables, as well as cooked ready-to-eat foods. 2013 FDA Food Code 3-302.11 changed the above to read, "frozen, commercially processed and packaged raw animal foods stored or displayed with frozen package ready-to-eat food is acceptable."[18]To prevent cross-contamination, no raw foods are to be stored above cooked or ready-to-eat foods.[5,7,23,24,25,26,27,28]

Key principles of food storage include:

- Store food only in designated areas, never in locker rooms, toilet areas, garbage rooms, mechanical rooms, under sewer lines (that are not adequately shielded), under open stairwells, or near any other source of contamination.[1,26]
- Store in clean wrappers or containers with covers; label contents appropriately with date item received.[1,6,24,26]
- If products are removed from original container that has the lot number, it is important to maintain lot numbers to be able to track and recall in the event of an identified problem.[1,6]
- Store eggs in original container in the refrigerator at 45°F.[7,18,27]
- Remove all corrugated cardboard as soon as possible, because these boxes may deteriorate or damage the product, the product may leak, or water damage may be present; any moisture rots the boxes, and these conditions allow for pest infestation and possible damage to the product.[1,18,26]
- Keep storage areas and vehicles to transport food clean. The area must have variable lighting, ventilation, and air circulation. A temperature range for dry storage is 50°F to 70°F (10°C to 21°C).[1,6,7]
- Low-temperature storage maintenance
  - Fruit and vegetables (except those in dry storage): 40°F to 45°F (4°C to 7°C)
  - Dairy products, eggs, meats, poultry, fish, and shellfish: 32°F to 40°F (0°C to 4°C)
  - Frozen foods: −10°F to 0°F (−23°C to −10°C)[1,6]

- Keep temperature logs of all storage areas; if a problem occurs, correct it and record the methods used to correct it; date, sign, and file.[1,6,8,10]
- Food must be stored 6 inches above the floor on clean racks with slatted shelves or racks that prevent cross-contamination and proper air circulation. Never cover the slats with foil or other materials as this prevents the flow of air.[1,6,26]
- Shelving must allow for cleaning under the bottom shelf or be flush with the floor and away from walls to facilitate cleaning and reduce places for pests to find refuge.[1,6,26]
- Storage shelves should be at least 2 inches from outside walls that may sweat because of differences between inside and outside temperatures. Food storage areas should have an established cleaning schedule to keep the area clean and minimize the risk of insects and rodents.[1,6,24,26]
- Implement cleaning schedules and monitor for cleanliness, temperature, ventilation, and pest infestation.[1,6,10]
- Never store toxic materials used for cleaning and sanitation in food storage area. Label and store in a locked area away from food and paper goods.[1,6,7,26]
- Use the FIFO procedure to rotate stock. Periodically check expiration dates on all food and supplies. It may be necessary to discard foods that are out of date. Food should be stored at the proper temperature, utilizing appropriate thermometers and maintaining temperature log records.[1,6,7,26,29,30,31]

Food Production System

The food production system must include safe handling of food products. The USDA Food Safety and Inspection Services (FSIS) provides safe handling tips in a program titled FightBac™.[28]It provides four guidelines to keep food safe:

- Clean: wash hands and work surfaces often
- Cook: cook to proper temperature
- Separate: don't cross-contaminate
- Chill: refrigerate promptly

Time and temperature is critical in protecting food in each step in the flow of food. Cooking (preparation and production) is an important step in the flow of food. When food is not properly prepared (e.g., such as not cooking thoroughly), a foodborne illness may occur. Cooking thoroughly destroys most, but not all, biological hazards. Reaching a specific temperature is not adequate to ensure the destruction of all pathogens.[18]Production personnel must hold the end temperature for a specific time. The Food Code states, "a combination of time and temperature to include the end temperature is required."[5]The end temperature is the temperature a food reaches at the end of cooking.[5,7]Check this temperature with a properly calibrated thermometer. Always use an appropriate thermometer to determine the internal temperature.[1,29,31]To measure the internal temperature of meat, place the thermometer in the thickest part of the meat without touching its bones. Insert sideways for thin items. Sanitize thermometer after each use using hot soapy water. Replace in holder and store.[31]

FDA Food Code 2013

Because the highest percentage of foodborne illness results from contaminated lettuce, tomatoes, salads, celery, coleslaw, and fruits such as melons, berries, and papaya, the FDA made the following changes in the 2013 Food Code, effective May 2013[18]:

Refrigerate cut leafy vegetables because of outbreaks of *Samonella*and enterohemhorragic *E. coli*. These foods are now considered hazardous.

- Although whole tomatoes may still be stored and ripened at room temperature, they must be refrigerated once cut or sliced. Recipes using cut tomatoes must be refrigerated. Processed foods containing cut tomatoes must be refrigerated unless the manufacturer does not require refrigeration.
- Leaves from leafy green vegetables should be removed from the head and cut, shredded, sliced, chopped, or torn. This standard does not include whole heads from which leaves were removed and discarded or fresh herbs such as cilantro or parsley. Handle fresh cut leafy greens with care, including washing. When washing, use running potable water. If soaked or “crisped,” potable running water rinse must follow. Keep refrigerated, as cut leafy greens are potentially dangerous foods.
- Chapter 3 NEW §3-401.14 Noncontinuous cooking is a new section providing parameters for cooking raw animal foods using a noncontinuous cooking process.[18]
    - Step 1: Up to 60 minutes initial heating process
    - Step 2: Cooling for 6 hours or less, then hold cold or frozen
    - Step 3: Prior to serving, cook to 165°F for 15 seconds
    - Step 4: Hold hot, cooled, or frozen

A written procedure must be available on-site. Procedures must have prior approval and include:

- Monitoring, corrective actions, and recordkeeping procedures
- System for marking undercooked animal food
- Separate to prevent cross contamination
- Sous-vide often involves a long, slow cooking process in a reduced-oxygen environment, creating a risk of bacterial growth caused to undercooking. Seal the product immediately before cooking. Variance and HACCP plan required for Sous-vide cooking.[18]
- Unattended cooking and hot holding is prohibited, unless monitoring is provided for cooking temperatures or oven temperatures.[18]Monitor for undercooking.
- Comminuted meat cannot be served raw or undercooked from a child’s menu. Raw or undercooked meat, eggs, seafood, and raw seed sprouts are currently prohibited on children’s menus and in preschools and elder care facilities.[18]
- Four or more eggs may not be pooled unless used in batters or pooled immediately before cooking. Raw eggs must be cooked immediately (within 30 minutes) after breaking. Pasteurized eggs are required if recipe contains four or more eggs and when not cooked within 30 minutes after pooling. New eggs broken for multiple customer orders must be cooked to 155°F (quiche, flan, buffet line scrambled eggs) and must be cooked within 30 minutes after breaking. Consumer advisory is still required if undercooking. Undercooking is still prohibited for establishments serving *only*highly susceptible populations; this includes preschool and elder care. Do not wash eggs.[18]

To Prevent Cross-contamination

Cross-contamination is the transfer of harmful bacteria to a food from other foods, cutting boards, utensils (especially spatulas), surfaces, hands, or poor hygiene. It is prevented by keeping food separate from contaminants by keeping hands, utensils, and food-handling surfaces clean.

- *Always*wash hands and bare arms with warm water (minimum temperature 100°F) before and after handling raw poultry or its juices. Clean and sanitize cutting board, utensils, sinks, and countertops.
- To avoid a buildup of bacteria, marinate in a refrigerator. *Never*use the marinated sauce on cooked meat, fish, or poultry unless it is first boiled (cooked). (Sauce used to marinate contains raw juices that can contain dangerous bacteria.)
- Follow hand-washing and glove-use procedures.[5,7]
- Observe the flow of food during preparation and keep raw foods separate from ready-to-eat foods.[5,7]

Formulas[32333435]

Reduce the risk of contamination when mixing formulas and enteral feedings by designating clean preparation areas. When possible, use commercially reconstituted formulas and feedings. The points below should be used if mixing products:

- Follow a concise procedure for the preparations, including a clean and sanitized work area.
- A foot-activated hand sink, liquid soap (NO bar soap), and one-use disposable towels
- A foot-activated garbage can
- Products should be placed in a clearly visible, labeled container.
- Use correct measurement tools when adding any product.
- After the formula is mixed, label with the name of the product, the date, and the initials of the employee who mixed the formula.
- Monitor compliance to the procedure(s) daily and record results of the cleaning procedures for all equipment, utensils, and work area.
- Train staff who prepare these formulas on safe, sanitary food-handling strategies.
- Consider having staff change from street clothing to department-required uniforms or covering. Hair must be completely covered with a disposable net, and disposable gloves must be worn during food handling.
- Encourage the use of prepared tube-feeding formula to reduce the risk of contamination.
- Never use raw eggs in a formula. If eggs are needed, use only pasteurized liquid or dry eggs.[1,18]

The FNS department is often responsible for delivering the prepared formulas/tube feedings to patient units. Disposable tube feeding equipment (bags, bottles, and tubing) should be used whenever possible, and any reusable bags/bottles must be discarded every 24 hours. The feeding formula that is not prepackaged should be discarded after hanging in a patient's room for 8 hours. Formulas reconstituted from powder have a 4-hour limit after hanging in a patient's room.[21]

The American Dietetic Association, with the American Academy of Pediatrics' endorsement, has published a book entitled *Infant Feedings: Guidelines for Preparation of Infant Formula and Breast Milk in Health Care Facilities*addressing reconstitution of formula.[35]Nursing personnel are usually responsible

for handling and administrating breast milk. Breast milk is a body fluid and is handled accordingly. A procedure should be in place in the event breast milk is administered to the wrong infant. If this occurs, it should be handled as an exposure event and risk management should be notified.[35]

Safe Handling

Food Code 2013 2-103.11(L) Employees are educated in food safety, including major food allergen ingredients and risk. All foods containing allergen must be labeled to include:

1. Name of food
2. Ingredients
3. Name and address of manufacturer or distributor
4. Quantity of contents

A packaging date code for freshness is important in case of a recall, particularly in the case of vending operations.[18]

Handle food with care and thoroughly cook at every stage of food preparation. The Food Code recommends that, “meat products should be thawed in a refrigerator at a temperature of 5°C (41°F) or less to 7°C (45°F) or less or submerged under running water to reduce microbial growth.”[5,18]Thawing and refreezing of meat products should be avoided. Using commercially filled, unopened packages (e.g., pasteurized milk and milk products, homogenized eggs or homogenized liquid eggs, tube feeding formula) whenever possible will reduce the potential for foodborne illness. “Cooking alone may not destroy all microorganisms or denature all toxins.” Some bacteria, such as *Staphylococcus*and several species of *Clostridium,*release toxins that are pathogenic and may not be inactivated at certain temperatures. Using the correct cooking temperatures for meat and poultry products will kill or reduce the number of microorganisms.[1,5,6,28]Some products have established minimum internal temperatures.

Examples include those shown in Table 109-1.

Many restaurant menus state that the ingestion of raw beef or seafood is at the risk of the customer. Many commercial food establishments will not serve raw beef and seafood. Undercooked foods can also pose a problem. Rare roast beef and rare beefsteak should be served only to populations that are not highly susceptible to foodborne disease. Healthcare facilities should not serve raw beef, seafood, or undercooked eggs to a customer.[18]

Table 109-1 Internal Cooking Temperature Specifications: Minimum Food Temperatures 2009 Food Code Update Bulletin

Temperature	Food

165°F for 15 sec

- Poultry (chicken, turkey, duck, goose)
- Wild game animals
- Raw eggs not for immediate service
- Stuffed fish, meats, pork, pasta, ratites (ostrich, rhea, and emu), and poultry
- Stuffing cooked alone or in the poultry
- Foods cooked in a microwave
- Sauces, gravy, and soups
- Leftovers
- Casseroles

155°F for 15 sec

- Ratites (ostrich, rhea, and emu)
- Injected meats
- Chopped or ground meat (veal, beef, pork), fish, or commercially raised game animals
- Mechanically tenderized meats
- Eggs on a steam table (yolks and whites are firm, not runny)

145°F for 15 sec

- Fish, except as listed above
- Meat, except as listed in other categories
- Commercially raised game animals, rabbits
- Raw eggs cooked for immediate service*
- All whole cuts of meats such as pork, steaks, roast, and chops

*Regulations require that yolks of fried eggs be cooked. Do not serve raw or uncooked eggs. Follow local and state regulations. (Eggs are refrigerated at 45°F)

The Food Code changed Potentially Hazardous Foods (PHF) to Time/Temperature for Food Safety Foods. These foods that are cooked and refrigerated should be reheated rapidly to 74°C (165°F) or higher for 15 seconds before serving.[18]All reduced-oxygen-packaging methods require controls for growth and/or toxin formation of *Clostridum botulinum*and *Listeria monocytogenes.*[18]

Wash raw fruits, including bananas, melons, and other hard-surface fruits and vegetables, under potable running water before serving or use.[1,7]Food Code 2013 now allows “the use of ozone in washing, treatment, storage, and processing of raw fruits and vegetables.”[18]A vegetable brush may be used to wash the outside coating of hard fruits and vegetables.[1]

Only food service workers should be permitted in the food preparation area. All other persons should have limited access and only if thy are conducting food service business. Traffic control of unauthorized individuals through food preparation and service areas will help to keep those areas clean and safe for food preparation.[1,5,18,32]

Microwave Cooking

When preparing food in a microwave oven follow the manufacturer's direction for wattage and time. General principles include:

- Place on a microwave-safe dish.
- Cover with wax paper or paper towel to retain surface moisture.
- Loosen or vent the lid to let steam escape (cooking bags promote safe, even cooking).
- Rotate or stir the food item as directed on package, usually at the midpoint of the cooking. This helps to distribute heat evenly.
- Use a thermometer to check the temperature of at least 165°F in all parts of the food item.
- Allow to stand covered (some directions state in the oven) before serving to obtain a consistent 165°F temperature.
- Partial cooking may be done in a microwave *only* if the food is to be finished cooking immediately, either on stove top, grill, or conventional oven.[1,7,36,37]

Prevention Strategies for Safe Food

Prevention strategies for reducing these risks can significantly reduce microorganism replication. These strategies include[1,5,6,7,9,10,18,34,35,36,37]:

- Labeling all food with the preparation date and time
- Not thawing and refreezing food products; keep product refrigerated or frozen
- Thawing of foods (1) under refrigeration in which food temperature is maintained at or below 41°F; (2) completely submerged under potable running water (at a water temperature of 70°F); (3) place food in a water type bag and submerge in cold water (change the water every 30 minutes); (4) as part of the cooking process; or (5) in a microwave and immediately transferred to conventional cooking equipment with no interruption in the process
- Not precooking and holding meats for final cooking (HACCP procedures must be in place)
- Chilling cooked perishable leftover foods to an internal temperature of 5°C (41°F) or less or to 7°C (45°F) or less within 2 to 4 hours of preparation
- Using shallow containers 2 to 4 inches deep for cooling hot foods to facilitate quick temperature reduction (140°F to 70°F within 2 hours and from 70°F to 40°F within 4 hours)
- Not stacking shallow pans on top of each other (allow air to circulate around foods being chilled)
- Rapidly reheating to 165°F within 2 hours
- Keeping hot foods at 135° or higher
- Stirring food while holding
- Do not pour a batch of new hot foods into a batch of hot food being served
- Not using hot food-holding equipment (such as steam tables) to reheat food

- Not reusing food or condiments that have been previously served to customers (butter, sauces, dressings, chips, or bread)
- Using sanitized, calibrated thermometers to monitor the temperatures, as required

Hold hot foods for serving at above 60°C/140°F (or higher). Hold cold foods for serving at 41°F or lower. The temperature danger zone is 41° F to 135°F, which is the temperature range for rapid multiplication of virtually all bacteria associated with foodborne disease.[1'567]Transport meal trays to patient units in temperature-controlled carts to keep food hot or cold. It is important to monitor these temperature-controlled carts and document that food is kept at the appropriate temperature during delivery.[1]

FNS takes every opportunity to reduce the introduction of microorganisms in dining areas, and patient meal service. Protect food from airborne contamination by using sneeze guards at salad bars and serving lines. Food that is purchased to be eaten elsewhere is placed in enclosed containers. Minimally handle patient food when distributing it to the patient. Cover all patient food especially when it is transported in an open cart.[1'6]

The interdisciplinary team in conjunction with FNS coordinates patient mealtimes with their scheduled therapy. Each patient unit has a specific time for meal carts to arrive on the patient unit. Nursing is to have the patient ready to eat when meal carts arrive on the unit. Serving trays may be a joint responsibility of nursing and FNS. The most efficient method is for FNS personnel to promptly serve the patient trays to ensure that foods are served at appropriate temperatures. When a patient is not in his or her room at mealtime, the tray should be replaced on the meal cart or in the unit nourishment room. FNS staff and nursing personnel need to make sure the food is maintained at a safe temperature. When the temperature is not maintained at a safe level, nursing may arrange for a new tray to be delivered to the patient. Soiled trays are to be removed from patient rooms within 1 hour after the meal is complete and returned to the dish room for cleaning, sanitizing, and storage for the next meal. Policies for safe times for food items to be stored in patient care are jointly developed by nursing and FNS. It is important to label contents and date when perishable food was placed in the floor/unit refrigerator. Perishable foods not consumed within 48 to 72 hours of preparation must be discarded, even when placed in appropriate refrigeration. After 24 hours, all open cans of nourishment left in a patient room must be discarded. On a daily basis, nursing or FNS needs to check floor refrigerators and discard any out-of-date items, paying close attention to any time/temperature control for safety foods.[1'6'7'18]

Personnel Policies

Personnel policies and procedures should include a monitoring procedure (e.g., employee health program) to ensure that FNS personnel report current illness. Food Code Chapter 2-2 outlines employee health standards, and the information must be included in department orientation and follow-up inservices. When there are breaches in policies, appropriate action needs to be taken and the outcome results must be documented. The latest issue of the Food Code states “In a verifiable manner, the employees are required to report information about their health and activities as they relate to diseases transmissible through food.”[5'18]

Hand Washing

A procedure demonstrating and monitoring proper hand washing technique is part of every FNS supervisor’s responsibility. Correct procedures for hand washing need to be a part of FNS employee

orientation and ongoing training.[1,6] Gloves are often required in combination with hand hygiene during food handling and processing, especially when handling foods such as raw fresh fruits and vegetables or ready-to-eat foods. When working with raw foods, employees should minimize bare hand and arm exposure and use suitable utensils, such as deli tissue, spatulas, tongs, single-use gloves, and dispensing equipment.[1,5,6,18]

The Food Code requires that hand sinks are available in or adjacent to restrooms and must be easily accessible to kitchen employees.[5,18] Health departments vary in the number of hand sinks in a kitchen. As a rule of thumb, plan on locating a sink every 15 feet to make it convenient for employees to use frequently. (Each facility will need to comply with local regulations.)

Hand-washing method:

1. Use flowing potable hot water of 110°F to 120°F to wet hands and bare arms (minimum water temperature is 100°F).
2. Apply antibacterial soap on hands, fingers, and bare arms.
3. Rub vigorously for at least 20 seconds.
4. Thoroughly rinse in flowing hot potable water.
5. As necessary, repeat Steps 1 and 2
6. Use a single towel to turn off the water. Use another towel to thoroughly dry hands and arms, as damp hands/arms spread more germs than dry hands/arms. Discard towel in garbage receptacle or keep to open the door. Dispose in garbage can located outside the door.
7. Where approved by state codes, use an electric hand dryer by rubbing hands under the forced warm air for approximately 30 seconds. Food Code 2013 states, “the use of a high-velocity blade non-heated pressurized air for hand drying is allowed.”[1,5,6,18]

When to wash hands and arms[1,6,18]:

- After removing contaminated gloves that are dirty/torn[5]
- After removing gloves for any reason
- Before handling food during preparation
- After handling food
- After cleaning a food preparation area
- After handling raw food (including meat, vegetables, or fruit) and preparing ready-to-eat foods
- After busing a table
- After contact with unclean equipment and work surfaces
- After contact with soiled clothing and wash clothes
- After using the restroom
- After using cleaners or chemicals
- After touching hair or face, and any time hands are visibly soiled
- After coughing, sneezing, using a handkerchief or disposable tissue, using tobacco, or eating or drinking
- After engaging in other activities, such as handling chemicals, taking out garbage, and working in dish room

Monitoring hand hygiene compliance is required for accreditation as a component of The Joint Commission National Patient Safety Goal No. 7.[38] In addition, the CDC states, "poor personal hygiene of foodservice employees, in particular improper hand washing, contributes significantly to the risk of foodborne illness. Improving foodservice employees' hand-washing practices is imperative in helping to prevent foodborne illness."[7]

Other important standards found in Food Coode 2009 and 2013 are:

- 2-301.11 Clean conditions
- 2-301.12 Cleaning Procedures
- 2-301.13 Special Hand Wash Procedures
- 2-301.14 When to Wash
- 2.301.15 Where to Wash
- 2.301.16 Hand Antiseptics
- 2 302.11 Maintenance (Fingernail care): Fingernail polish or artificial fingernails may not be worn when working with food unless wearing intact gloves.
- 2.303.11 Jewelry (no jewelry except for a plain ring such as a wedding band may be worn while preparing food).
- 2.304.11 Outer Clothing. Food employees shall wear clean outer clothing to prevent contamination of food, equipment, utensils, linen, and single-service and single use articles.[5,7]

Holding and Serving Prepared Foods

An improper storage or holding temperature is the most common practice associated with a foodborne illness. Organisms that are naturally present in food or introduced during processing or handling can thrive and proliferate under improper conditions. Foodborne bacteria can replicate and may produce food-related infections or toxicity. Key factors leading to foodborne contamination and disease include failure to use food within an appropriate amount of time after preparing it, failure to maintain or store food at an appropriate temperature, or unsanitary methods of displaying and serving food.[1,5,6,36]

Cold foods must be held at 41°F or lower; at this temperature the growth of bacteria is slowed. Do not store packaged products (sandwiches) in direct contact with ice or water if water could enter the packaged product.

Cool food from 135°F to 41°F within a maximum of 6 hours. The first step is to get the food to 70°F within the first 2 hours and then to 41°F in the next 4 hours. To accomplish this reduction, follow these steps[36]:

- Place food in a shallow container (2 inches deep) to increase the surface area and reduce cooling time.
- Divide a large piece of meat or large mass of food into several pieces.
- Stir the food in a container placed in an ice bath.
- Use a blast chiller for rapid cooling.
- Add ice to the ingredients

After properly cooling the food cover, label, date, and refrigerate at 41°F or lower. Food must be discarded if not used by the indicated date.[1,5,6,36]

Ice

Written procedures to prevent ice contamination include[1,6,10,39]:

- Use only potable water to manufacture ice.
- Store ice in a covered ice bin; keep covered when not in use.
- Wash hands before scooping, as freezing temperatures do not destroy all pathogens.
- Use nonbreakable scoop (never glass); store the scoop following local regulations, but never in the ice bin on top of the ice; clean and sanitize daily by running through the dish machine.
- Do not store food or beverages in the ice bins.
- Frequently clean the bin.
- Keep ice bin covered to protect ice from broken glass, china, and chemicals. Do not allow unauthorized personal use.
- Ice used for display of cold foods is not to be used for any other source. Once ice is used, including clean-up, discard it.

Overproduction

Overproduction results in leftovers. FNS will need to develop written policies to address the disposition of over produced food items. To reduce contamination and possible foodborne illness, leftovers need to be properly handled, stored, and dated/labeled (how and when to use, and when to discard).[1]A few examples include:

- Discard foods that have been at room temperature for more than 2 hours.
- Quickly chill (see above) or separate into large protions into smaller portions before refrigerating.
- Label with the date when food should be used or discarded. Use these foods within 7 days when stored at or below 41°F. If the foods are not used within the storage time, discard the foods.
- When using leftovers in their original form, reheat to 165°F for at least 15 seconds.
- Do not heat leftovers more than once. Discard remaining leftovers after first heating.
- When adding leftovers to a new food product, such as soup, do not add until soup is heated; then heat the entire product to165°F.
- When in doubt about the quality of the food, discard it.[1,5,6,36]

Hazard Analysis and Critical Control Point

The National Aeronautics and Space Administration (NASA) and the U.S. Army Natick Research Laboratories developed HACCP in 1960. In 1971, the Pillsbury Company in cooperation with NASA and Natick Research Laboratories improved the process. In 1988, the National Advisory Committee on Microbiological Criteria for Foods took over the HACCP. HACCP is a prevention-based food safety system designed to prevent the occurrence of food safety problems. Like many other quality assurance programs, HACCP provides a common sense approach to identifying and controlling problems that likely exist in an operation.[1]

HACCP is used throughout the food industry and can be useful in the FNS department. HACCP is a system that identifies and monitors specific hazards—biological, chemical, or physical properties—that can adversely affect the safety of the food product. This hazard analysis serves as the basis for establishing critical control points (CCPs). CCPs identify the points in the process that must be controlled to ensure the safety of the food. In addition, critical limits are established that document the appropriate parameters that must be met at each CCP. Monitoring and verification steps are included in the system, again to ensure that potential risks are controlled. The hazard analysis, CCPs and critical limits, and monitoring and verification steps are documented in a HACCP plan.

HACCP comprises seven principles that provide guidelines on the development of an effective HACCP plan.[4041424344]

Principle 1: Analyze Hazards

The HACCP team begins by identifying the potentially hazardous food/temperature control for safety (PHF/TCS) foods on each day of the menu cycle. The hazard analysis is performed for five purposes:

- Identify any hazard of significance from growing to plate
- Provide a risk basis for selecting likely hazards
- Identify hazards that can be used to develop preventive measures for a process or product to ensure or improve food safety of the process product
- Identify food allergens
- Identify environmental contaminants (chemicals) and physical hazards

Principle 2: Identify the CCPs

A CCP is a point, step, or procedure in which control is applied and a food safety hazard is prevented, eliminated, or corrected to within acceptable levels. According to the USDA, a specific food system may present an unacceptable health risk where there is a loss of control during critical control points or procedures. Points in food preparation that may be CCPs include:

- Cooking, chilling, receiving, mixing ingredients, and other food handling procedures
- Food procurement, including source of supply and condition of food on receipt
- Food distribution
- Food display
- Employee health, hygiene, and education
- Refrigeration or the adjustment of a food's pH to a level required to prevent hazardous microorganisms from multiplying or toxins from forming

Principle 3: Establish Critical Limits for CCP

The procedures to prevent, reduce, or eliminate hazards are determined at this step, and quality and safety limits are established. A critical limit is a prescribed parameter (e.g., minimum or maximum value) that must be met to ensure that food safety hazards are controlled at each CCP. CCPs include:

- Time and temperatures parameters
- Time humidity
- Water activity (aw), pH

- Preservation, salt concentration
- Available chlorine, viscosity
- Hand washing, illness of personnel
- Storage, preparation, and service
- Temperatures for preparation, holding, and service
- Appropriate use of leftovers and rethermalization

Principle 4: Establish Procedures to Monitor CCPs

Monitoring is a planned sequence of observations of measurements to assess whether a CCP is under control and to produce an accurate record for use in further verification procedures. There are three main purposes for monitoring:

- It tracks the system's operation so that a trend toward a loss of control is recognized and corrective action can be taken to bring the process back to control before a deviation occurs.
- It indicates when a loss of control and a deviation have actually occurred and corrective action is taken.
- It provides written documentation for use in verification of the HACCP plan.

The team decides who will be responsible for monitoring the critical limits, as well as what forms are used to document the activities and the methods to use to inform the staff of the monitoring activities. All information gathered must be objective and measurable. The monitoring procedures track the system or process of operation.

Principle 5: Establish Corrective Actions

Corrective actions are activities taken whenever a critical limit is not met. Corrective actions should determine and correct the cause of noncompliance, determine the disposition of the noncompliant product, and record the corrective actions taken.

Principle 6: Establish a Recordkeeping System

The following are some examples of HACCP plan verification activities used as part of an HACCP program:

- Establishment of appropriate verification inspection schedules
- Review of the HACCP plan
- Review of the operation to check that CCPs are under control and monitoring is effective
- Review of deviations and their resolutions, including disposition of food
- Visual inspections of operations to observe if CCPs are under control
- Random sample collection and analysis
- Self-checking audits
- Check the system when changes are made such as new products, new procedures, new suppliers, and any other changes occur.

Principle 7: Establish Procedures to Verify the System Is Working

This principle requires the preparation and maintenance of a written HACCP plan by the food establishment. The plan must detail the hazards of each individual or categorical product covered by the plan. It must clearly identify the CCPs and the critical limits for each CCP. CCP monitoring and recordkeeping procedures must be included in the establishment's HACCP plan. An implementation strategy is a part of the food establishment's documentation. Follow-up studies and a permanent control program need to be established. Verification and auditing can verify the HACCP system is working correctly and achieving the desired result.

Emergency Management Preparedness

Surveying agencies such as CMS and TJC have established standards for emergency management preparedness. State and local agencies have regulations for the amount of food and potable water to have on hand in case of an emergency (usually, a 72-hour supply); these procedures need to be followed. All personnel need training for their responsibilities during a crisis/emergency. The FNS departments have written plans that are a major part of the facility plan. These plans are included in an all-facility exercise, with emphasis on how food, potable water, and meal trays would be supplied to patients, staff, and others. To augment the facility exercise, FNS uses an exercise called "tabletop planning" in which potential scenarios and planning are discussed by the interdisciplinary team without a simulation exercise.[1,4,5,4,6,4,7]

Specific steps that FNS will take in anticipation of an emergency include:

1. Monitoring the amount of emergency supplies on hand and comparing that to projected need
2. Following state and local regulations concerning the amount of food and water required per population
3. Checking availability of water purifying materials
4. Checking operation of flashlights and ensuring that a backup supply of batteries is on hand
5. Reviewing employee addresses and phone numbers and updating call backlists
6. Monitoring sanitation for needed supplies and correct storage. Checking supplies for FIFO and rotating supplies as needed.[1]
7. Reviewing emergency response protocols with HCP.

During a disaster, it is a priority to provide drinking water and food to patients and HCP. FNS is often responsible for this critical service of providing potable water and for planning for alternative sources and/or methods to purify water. Potable water is required for drinking, food preparation, and cleaning. FNS's emergency response plan needs to address a plethora of areas, including external and internal departmental communications; adequate staffing for the projected need; procedures for safety, sanitation, and security of food, water, and HCP; management of unauthorized people who enter the department; and management of the clinical role for medical nutrition therapy.[1,4,5,4,6,4,7,4,8]

FNS must work closely work with approved suppliers through procurement contracts for delivery of food and water in an emergency and for establishing stockpile/storage of emergency supplies. Special considerations for food preparation, safety, and delivery must be given when there is an electrical outage, including methods for delivering patient food trays to various floors. Provisions for safely preparing baby formulas and enteral formulas also need to be addressed.[6,3,5]In addition, strategies to meet refrigeration needs, such as having access to a refrigerated truck, would be important to identify in contracts and services before the incident. If refrigerated trucks are not available, the processes for handling food under those circumstances should be included in written emergency plans. Maintaining a stock of disposable dishes, utensils, and cups will be useful when dishwashing systems are not

functioning. Waterless hand sanitizers in compliance with FDA guidelines may be used for hand hygiene during times of emergency. The product should be easy to use with a pleasant or nonirritating smell. The use of bar hand soap is highly discouraged.[1'18'444546]

Food Safety and Recall

The USDA Food Safety and Inspection notifies the public of a recall. Suppliers may also notify the facility. Items for recall should be separated in the storeroom from products that may be used. Ensure that the product is *not* used. Follow the recall procedure of discarding or returning the product to the supplier.

Cleaning, Sanitizing, and Equipment Maintenance

New standards for the maintenance of equipment, utensils, and linens have been added to Food Code 2013, primarily to align the standards with the EPA terminology and procedures.[49] Table 109-2 identifies changes in chemicals and temperature for sanitation. Another significant change addresses the rinsing of equipment and utensils after being cleaned and sanitized summarized in the steps below.[18]

1. The rinse is applied directly from a potable water supply by a warewashing machine that is maintained and operated as specified in the Food Code.
2. The rinse is applied *only* after the equipment and utensils have been sanitized by application of hot water or by application of a chemical sanitizer solution whose EPA-registered label instructions call for rinsing off the sanitizer after it is applied in a commercial warewashing machine.[22'50]

Table 109-2 Examples of Chemical Sanitizers and Time/Temperature Requirements

Minimum Concentration	Minimum Temperature	Minimum Contact Time *
Chlorine 25 ppm	120°F	10 sec
Chlorine 50–100 ppm	75°F–115°F	30 sec
Chlorine 100 ppm	55°F	10 sec
Iodine 12.5–25 ppm	75°F–120°F minimum 75°F–68°F	30 sec
Quaternary ammonium 180–200 ppm	75°F (minimum)	30 sec

**Contact time shall be consistent with EPA-registered labeling and to harmonize with EPA terminology.*[56]

The selection of products for cleaning and sanitation is important. Select products for specific purposes. Collaborate with the cleaning supply company for recommendations, especially for ware washing and overall cleaning procedures.[50515253]

The use of poorly designed or old equipment that is difficult to clean is more likely to spread microorganisms. Equipment that has cracked and chipped surfaces should not be used. All employees need to be educated and trained for appropriate cleaning and sanitation systems. FNS management should continuously monitor the appropriate use of equipment and cleaning compounds according to manufacturer's recommendations. Scheduled maintenance and cleaning schedules must be followed with routine inspections to ensure that equipment is properly working. A material safety data sheet for all cleaning compounds should be kept on file and accessible as a reference to all HCP.[54] Improper use of cleaning and sanitizing chemicals or equipment may not reduce microorganisms to acceptable levels. Cleaning compounds should be stored separately from food, insecticides, rodenticides, and other poisons.[1'5'6'535554]

Proper use, cleaning, and sanitizing of cutting boards is essential to prevent cross-contamination. Cutting boards are to be nonabsorbent. The preferred materials for cutting boards include plastic blocks, hard rubber, and nonabsorbent wood. Always use a clean cutting board for food preparation. It is optimal to have separate cutting boards for meat, poultry, and fish; raw fruits and vegetables; and cooked foods. Follow procedures to adequately clean and sanitize each board between uses as a way to help prevent cross-contamination. Replace cutting boards that have become excessively worn or develop hard-to-clean grooves.[1,2,5,6,7,54]

A clean environment is vital to good sanitation practices. Maintaining a clean environment for food preparation is an important part of a food safety and sanitation program. If FNS fails to use appropriate cleaning and sanitizing techniques, the presence of bacteria and the likelihood of foodborne illness increases. A basic principle to cleaning in FNS is “clean as you go.” Clean and sanitize any surface to which food is exposed. This includes dishes, utensils, pots, and pans. Clean all work surfaces, utensils, and equipment thoroughly by rinsing and sanitizing after each use, according to manufacturer’s directions. Cleaning schedules should include the time to be cleaned, the procedure for cleaning, and the type of chemical to be used in the cleaning. Cleaning schedules should be posted in a location visible to the HCP. Cleaning consists of removing gross food and other organic matter from working surfaces, utensils, and equipment using potable water. Cloths used for wiping food spills should be used for no other purpose. Wet cloths used for wiping should be stored in a sanitizing solution.[1,7,50,51,52]

A ready supply of potable hot water (120°F to 140°F [49°C to 60°C]) must always be available. Check the water temperature in dishwashing machines prior to use to ensure that it is sufficient to clean and sanitize. Chemical strips may be used to determine the temperature of the water. Be sure to follow the manufacturer’s direction for each phase of the wash and rinse cycle temperature. Keep all parts of the machine clean, including any removable parts.[1]Recommendations for temperatures by wash cycle are:

- Prewash: 110°F to 120°F (use appropriate cleaning agent)
- Wash: 140°F or greater
- Rinse: 160°F or greater
- Final rinse: 180°F

The most commonly used sanitizers are chemicals and heat. It is important to select appropriate disinfectants, sanitizers, and detergents as an intervention in preventing foodborne illness. Use a systematic evaluation of products when selecting a sanitizer for use in the FNS department. The FNS leadership needs to know where and how the sanitizer is used, as well as the properties of the water and the equipment, if any, where it will be used. Select products that meet the department’s needs. Chemical sanitizers are affected by time of exposure, pH, temperature, and water hardness.[1,6,7]

Examples of commonly used chemical sanitizers and time/temperature requirements are in Table 109-2.

Heat sanitizers, either moist or dry, require a minimum temperature and exposure time. Table 109-3 gives examples of commonly used heat sanitizers and minimum contact time.

Table 109-3 Commonly Used Heat Sanitizers

Medium	Temperature	Minimum Contact Time
Steam	200°F	5 min
Water	170°F	5–20 min
Dry heat	180°F	20 min

FDA Code Cleaned food contact surfaces can be sanitized by immersion in water that is 171°F or above for at least 30 seconds.

The competency of food service workers is essential to ensuring food safety and sanitation. They should be trained in all procedures for cleaning and sanitation, including the proper mixing and use of chemical and heat sanitizers. Procedures should also be available in a hard copy text for quick reference. Training records containing topic, objectives, length of training, name of instructor, and participant should be maintained and filed in the FNS administrative office.[1,5,6,56]

Dishes should be air dried—never dried with a cloth. Air-dried dishes should be stored in a clean dust-free area protected from splashes, spills, pests, and other forms of contamination.[1,6,7]Avoid stacking utensils within one another until they are completely dry. Cups and glasses are stored in an inverted position.

Vending Machine Guidelines[57,58]

All vending machines must comply with National Automatic Merchandising Association, National Sanitation Foundation (NSF), federal, state, and local codes. Vending machines may be self-operated or sourced out to a vending company. Regardless of who oversees the vending operation, food quality, equipment operation, and maintenance and vending area sanitation, temperature control, safety of food, and out-of-date products are a major concern. If a vending company operates the machines, strict written polices delineating the FNS and company responsibilities must be established. If self-operated, FNS must have written procedures for the operation.

All machines, except those that dispense canned sodas, must have an overheat protection. If not protected from the outside elements, the dispensing compartment of a vending machine must be equipped with a self-closing door.[59]

Vending machines should be located in an area that provides space around and under equipment to facilitate cleaning and maintenance.[1,6,7]Food in the machine should be stored and packaged in clean, protective containers; handled, transported, and vended in a sanitary manner; packaged in single-service containers with expiration dates; and refrigerated or heated and held at correct temperatures (41°F or below for cold foods and 135°F or above for hot foods). The exceptions includes the 30-minute recovery period after loading or servicing and the 120 minutes to heat foods through the 41°F to 135°F temperature zone.[7]Appropriate temperatures are maintained once food is heated and should be maintained until food is served or discarded.[57]

Containers must be kept cleaned and sanitized when used to transfer bulk foods products to machines.

Thermostatic controls should provide adequate refrigeration or heating units or both; ensure the maintenance of applicable temperatures at all times; and prevent the machine from vending the food until serviced by the operator in the event of temperature failure.[7]The thermometers are easily readable and are accurate to ± 3°F. An automatic shutoff should be located in each machine so that the machine shuts off automatically when temperature reaches the danger zone.

PHFs should be held no longer than 24 hours and be labeled with the preparation date and the date when the food is to be consumed, usually no more than 7 days from the date of preparation. Ready-to-eat foods should be discarded within 7 days of preparation when not consumed. All vended PHFs must

be in original containers as packaged at the preparation center. Condiments need to be in individual packets. All food must be labeled in accordance with Code of Federal Regulation, Title 21.[58]

Vending equipment must be cleaned and sanitized at least daily. Clean and sanitize all parts of the vending machine that come into direct contact with other PHF by methods approved by the local health authority.[58,60]The exterior construction and surfaces of the equipment should be easy to clean and limit the entrance of insects and rodents. Equipment should be located in such a manner that the space around and under the machine can be easily cleaned and maintained. The interior surfaces and component parts should be made of smooth, nontoxic, corrosion-resistant material, capable of withstanding repeated cleaning and sanitizing, and protected from normal manual contacts, dust, insects, rodents, and other contaminants.[58,60]

The vending machine attendant must conform to hygienic practices while engaged in handling food, food-contact surfaces, utensils, or equipment. Tobacco products in any form are not used while handling food. Personnel with boils, infected wounds, or acute respiratory infections should be restricted from work if there is a likelihood of contaminating food or food-contact surfaces. IPs should be aware of the local or state agencies with authority over vending machines and monitor following established guidelines.[5,18]

Conclusions

FNS is a key partner in infection prevention, and through its efforts in providing safe food and potable water, it builds a foundation for good nutrition that promotes healing and wellness. Foodborne illness can be significantly reduced and prevented when basic sanitation procedures and local, state, and federal food regulations are followed. The first step in prevention is having policies and procedures in place for safe food handling and personal hygiene and complying with them. Staff education and compliance monitoring are important to ensure consistent and safe practices. FNS department staff should stay abreast of current events related to changes in Food Codes, food contamination, recalls, and outbreaks so they can quickly assess their stock and take appropriate action. Vigilance in following HACCP guidelines strengthens infection prevention efforts. Many FNS departments have the responsibility to feed and nourish patients and staff during times of crisis. It is in the best interests of the customers of FNS for the department to plan for emergencies and test its plans to improve their overall capacity to effectively respond.

International Perspective

The globalization of the food supply has led to rapid and wide spread international distribution of food pathogens that can inadvertently be introduced into new geographic areas. Travelers, refugees, and immigrants may be exposed to unfamiliar foodborne hazards in new environments. Changes in microorganisms lead to constant evolution of new pathogens, development of antibiotic resistance, and changes in virulence of know pathogens. In many countries as people increasingly consume food prepared outside of the home, growing numbers are potentially exposed to poor hygiene and potentially exposed risk of poor hygiene in community foodservice settings.[61]

The world is a smaller place today because of increased international flights for tourists and expanded international commerce, both of which make the potential for foodborne illness a major public health

concern worldwide. An international focus on improving food safety must include these elements to identify and reduce risks: improved surveillance, community education, thorough understanding of the food production chain, use of HACCP strategies, and access to ionizing radiation. The ISO 22000 is a generic food safety management that defines a set of general food safety requirements that apply to all organizations that use HACCP.[62] ISO 22000 uses HACCP to help improve conditions that must be established throughout the entire food chain and the activities and practices that must be performed to establish a hygienic environment.[1] As ISO works with growers, producers, and others in the food chain, it is hopeful that the incidence of foodborne illnesses will decline.[62]

The ISO 22000 will take the collaborative efforts of primary care physicians, FNS, IPs, and public health to establish an effective surveillance and early reporting methodology. These professionals also have a crucial role in educating the public on the importance of basic food safety. The ten most common foods causing foodborne illness, and the most commonly associated organism, in the United States and Canada for the last decade have been listed as[59]:

1. Cantaloupes from Mexico and the United States (*Salmonella*)
2. Ground turkey (*Salmonella*)
3. Eggs (*Salmonella*)
4. Cut celery (*Listeria*)
5. Red peppers from Mexico (*Salmonella*)
6. Peanut butter (*Salmonella*)
7. Spinach (*E. coli*)
8. Tomatoes (*Salmonella*)
9. Roma tomatoes, pre-sliced (*Salmonella*)
10. Deli meat especially sliced turkey (*Listeria*)

In the United States, there have been other major recalls for ground beef (*E. coli*) and chicken (*Salmonella*). Worldwide there are still concerns for typhoid fever, *Listeria*, *E. coli,* and other emerging pathogens. *Salmonella* is the leading cause of foodborne illnesses.[8]

To assist in preventing this global problem, a culture change is necessary. The following suggestions could help in the development of quality improvement program:

- Fully implement the ISO 22000/HACCP program.
- Evaluate farms, slaughterhouses, processing plants, and delivery systems to assess conditions where outbreaks have occurred and, if necessary, shut them down.
- Provide education and training at all steps in the "farm-to-the-table."
- Evaluate temperature maintenance at all steps in the "farm-to-the-table."
- Teach and monitor personal hygiene of employees to include working while ill and above all proper hand-washing procedures.

Abstract

*Since the 1970s, there have been multiple instances of quality problems (e.g., microbial contamination, concentration errors, or pyogenic responses due to endotoxins) associated with compounded sterile and nonsterile pharmacy preparations, many of which resulted in recalls, patient injuries, and deaths.*Between January 2000 and before the 2012 nationwide fungal meningitis outbreak, at least 11 outbreaks were identified, involving 207 infected patients and 17 deaths after exposure to contaminated compounded drugs.[1,2]*Pharmacists and pharmacy technicians are the professionals primarily responsible for the preparation and storage of compounded sterile and nonsterile preparations. Compounding is the process of combining drug ingredients to prepare medications that are not commercially available (i.e.,*

neonate, pediatric, and geriatric dosage forms or ongoing manufacturer-related drug shortages) or to alter commercially available medications to meet specific patient needs, such as dye-free or liquid formulations.[3]*Failure to follow sterile compounding standards*[3]*and proper aseptic technique has lead to intrinsic (i.e., contamination during the manufacturing process or transport to the healthcare facility) or extrinsic (i.e., contamination during preparation, storage, or administration within the healthcare facility or practitioner's office) contamination, which may result in microbial colonization or infection in the patient.*

Pharmacy management personnel should participate in identifying staff who would benefit from education and proficiency evaluation of their aseptic technique and compounding procedures and calculations and, when necessary, to coordinate any medication recalls and traceability to the patients who have received specific products associated with medication errors, endemics, and epidemics. This should include both pharmacy personnel and other clinicians who may compound sterile preparations (including those intended for immediate use), such as anesthesia practitioners, nurses in oncology and other clinics, personnel in allergist offices, dialysis nurses and technicians, etc. A contaminated infusate administered through a central venous catheter is a rare cause of catheter-associated sepsis but one of the most readily identifiable causes of epidemic healthcare-associated bacteremia associated typically with one organism. Because it is not routine to culture infusate specimens in a diagnostic evaluation for a central venous catheter–associated infection unless there is strong evidence, many episodes of infusate-contaminated infections may go undetected unless they are part of a cluster of infections in a discrete patient population (e.g., hospital) or in the early stages of an epidemic.[4]

Pharmacy personnel are responsible for coordinating recalls of pharmaceutical preparations, such as occurs in cases of intrinsic contamination or due to other quality deficiencies (e.g., unacceptable particulate matter or potency). Pharmacists and technicians can be instrumental when they participate in multidisciplinary activities, such as quality assurance and quality improvement teams, infection prevention committees, and antimicrobial stewardship programs, to ensure appropriate preparation and use of pharmaceuticals.

Key Concepts

- Risks associated with microbial contamination of compounded sterile preparations
- Modes of extrinsic contamination of compounded sterile preparations
- Methods for preventing extrinsic contamination of compounded sterile preparations
- Pharmacy oversight involving antimicrobial stewardship
- Collaboration with infection preventionists

Background

Significant patient morbidity and mortality have resulted from both intrinsically and extrinsically contaminated compounded sterile preparations.2Most of these events have been related to extrinsically compounded sterile preparations. Pharmacy is primarily responsible for the handling, preparation, and storage of compounded sterile and nonsterile preparations. Respiratory therapists, nuclear medicine technologists, nurses, anesthesia practitioners, dialysis technicians, physician assistants, and physicians also prepare compounded sterile and nonsterile preparations. Pharmacy needs to actively participate in the aseptic training of these persons. Pharmacy personnel need to participate as members of the

healthcare team when identifying patients who have received specific compounded sterile preparations associated with outbreaks of endemic and epidemic infusate-associated bloodstream infections (BSIs). Pharmacy personnel are responsible for coordinating recalls of pharmaceutical preparations, such as occurs in cases of intrinsic contamination. Other responsibilities of pharmacists include providing clinical care of patients, distribution of oral solid and liquid dosage forms, managing intravenous (IV) therapy teams, preparing compounded sterile preparations for patients receiving home IV therapy, and oversight of policies and practices for administering medications. The pharmacy department provides oversight of the safe and effective use of medications in other areas of the institution (e.g., therapeutic interchange, medication reconciliation, reviews of medication orders to ensure that they are clinically and therapeutically appropriate, and inspections of patient care areas in the search for outdated medication and to ensure the appropriate storage conditions of medications via monitoring of refrigerated medication storage space). The pharmacy also provides information on pharmaceuticals, including indications, dosage, and route of administration; contraindications; adverse effects; drug interactions; and proper storage. Increasingly, pharmacy is part of the antibiotic/anti-infectives stewardship program designed to ensure proper use of antibiotics (appropriate drug[s], dose, and duration) and safest possible drug(s) and to minimize the risk of precipitating antibiotic-resistant pathogens, collateral damage (e.g., *Clostridium difficile*disease), and costs.

Pharmacy personnel are not at high risk for occupational exposure to infectious diseases unless they are involved in direct patient care, such as during cardiac arrest response. The pharmacy should work with the infection prevention and occupational health departments in managing employee exposure to potentially contagious patients and selecting appropriate postexposure prophylactic agents. Pharmacists may be involved in advocating and administering immunizations (e.g., influenza, diphtheria-tetanus toxoid-acellular pertussis, and pneumococcal vaccines). Pharmacists and technicians working within a healthcare facility should be immune to mumps, measles, rubella, varicella, hepatitis B, and pertussis. Immunity may be demonstrated by physician-diagnosed disease (mumps, measles, varicella), serology (mumps, measles, rubella, varicella, hepatitis B), self-history of disease (varicella), or appropriate immunization (all). All pharmacy personnel should receive annual influenza vaccine unless contraindicated.

There is an important parallel and intersection between pharmacy and infection prevention. First, as it relates to the ongoing management of critical environments where sterile compounding is conducted, pharmacists should work closely with infection preventionists (IPs) to ensure that potential sources of environmental contamination are identified during routine environmental monitoring (i.e., air surface and gloved fingertip sampling) and remediated as needed. Critical compounding environments need to be cleaned and disinfected with appropriate equipment (e.g., microfiber mops and low-linting wipes) and germicidal agents so IPs can provide critical insight and assistance to maintain a state of control in these environments.

Second, the pharmacist conducts surveillance of antimicrobial utilization even as IPs monitor pathogens. The value of collaboration is the ongoing assessment and analyses of the impact of utilization patterns on the emergence (hopefully regression) of multidrug-resistant organisms (MDROs) and microbes of epidemiologic importance. The related activities support and enhance the increasing attention to antimicrobial stewardship programs that demonstrate greatest success when developed as a team effort.

Basic Principles

Contamination of infusates is believed to be an uncommon cause of infections but has resulted in episodes of Gram-negative rod (GNR) bacteremia in individual patients and epidemics.[2,5,6] True incidence of infections related to contaminated infusates is not known. There are two sources of contamination. Intrinsic contamination (that which occurs during the manufacturing process) and extrinsic contamination (that which occurs subsequent to manufacturing, during aseptic manipulations, or while the infusate is in use) of infusates are a less common cause of infection than is cannula-associated contamination but are more likely to result in bacteremia and septic shock.[5] In October 2008, the Society for Healthcare Epidemiology of America and the Infectious Diseases Society of America published a compendium of practice recommendations targeted at the prevention of healthcare-associated infections (HAIs).[7] This publication is in the process of revision and is expected to be released in 2014. This compendium was revised by many healthcare organizations, professional associations, government and accrediting agencies, legislators, regulators, payers, and consumer advocacy groups that have advanced the prevention of HAI as a national imperative. These external pressures have also had an impact on pharmacy practices, as maximizing patient safety remains a critical component of any medication delivery system involved with preparing compounded sterile preparations.[7] In 2004, the United States Pharmacopeial (USP) Convention published the first national and enforceable standards for compounded sterile preparations (i.e., General Chapter 797-Pharmaceutical Compounding-Sterile Preparations).[3] In 2012, both the Centers for Disease Control and Prevention (CDC) and the Centers for Medicare & Medicaid Services acknowledged the importance of the USP chapter in protecting patients against preventable harm from improper use of single-dose/single-use vials.[8,9]

Intrinsic Contamination

Intrinsic and extrinsic contaminations are differentiated based on epidemiologic data. Bacteremia caused by the infusion of contaminated fluids is less common but nevertheless is a potentially serious problem that can affect one patient or dozens depending on the circumstances of contamination (i.e., infusates prepared by nurses versus prepared in the pharmacy).[10] Most healthcare-associated epidemics of infusion-associated septicemia resulting from intrinsic or extrinsic contamination are caused by aerobic Gram-negative bacteria.[11] Pathogens implicated include the Enterobacteriaceae such as *Klebsiella, Enterobacter, Serratia* spp., and *Citrobacter freundii*, and also the nonenterics *Burkholderia cepacia* and *Ralstonia pickettii*.[5,6,11] However, disease can result from intrinsic contamination of medication by endotoxin without the presence of viable bacteria.[12,13]

Intrinsic contamination of infusate has led to epidemics of healthcare-associated sepsis.[5,14,15] Intrinsic contamination of parenteral medications with endotoxin caused an epidemic of clinical sepsis in a newborn nursery.[16] Epidemics of *Candida parapsilosis* and *C. albicans* fungemia have been related to use of contaminated parenteral nutrition (PN).[17,18,19] Epidemics of septicemia caused by *Staphylococcus saprophyticus* and *Enterobacter cloacae* have resulted from contamination of PN admixtures during compounding or storage.[20]

Extrinsic Contamination

Clusters of postoperative infections have been associated with extrinsic contamination of propofol, an IV hypnotic agent in a 1 percent lipid emulsion; organisms isolated include *S. aureus, C. albicans, Moraxella osloensis, Enterobacter agglomerans*, and *Serratia marcescens*.[21,22,23] There have been

recalls and subsequent shortages of propofol due to the presence of elevated endotoxin levels.[24] An outbreak of severe sepsis (systemic inflammatory response syndrome) occurred in seven postoperative patients in The Netherlands and was related to propofol contaminated with *Klebsiella pneumoniae* and *S. marcescens*.[25]

An outbreak of *E. cloacae* BSIs was associated with contaminated prefilled saline syringes prepared by a home-infusion company distributing to 20 states.[26] Five cases of Hepatitis C were attributed to diversion of fentanyl by healthcare personnel (HCP) infected with Hepatitis C virus (HCV). The diversion of fentanyl resulted in contamination of syringes with HCV, and other HCP subsequently used these syringes to administer fentanyl to patients.[27] Intentional tampering or division must always be considered when an epidemic evaluation of an outbreak implicates extrinsically contaminated narcotics or other controlled substances.

In-use IV fluids have contamination rates of 0.9 to 7.8 percent.[10,28,29,30] The most common organisms found are coagulase-negative staphylococci. However, GNRs have been found in these infusate solutions. In addition, free endotoxin was found in 2.5 percent.[29] In-use syringes of propofol have shown contamination rates of 5.1 percent (19/376) and 5.6 percent (18/302).[31,32]

Commonly prepared compounded-sterile products are susceptible to microbial contamination. Specific microorganisms have the ability to proliferate in different fluids. *Klebsiella, Serratia*, and *Enterobacter* spp. and *Burkholderia cepacia* can multiply in 5 percent dextrose.[5] *C. albicans* can grow slowly,[5] whereas *Staphylococcus, Proteus, Escherichia coli, Herellea*, and *Pseudomonas aeruginosa* die slowly in dextrose.[33] *Burkholderia cepacia, Pseudomonas aeruginosa, Acinetobacter*, and *Serratia* will grow in distilled water.[5] *P. aeruginosa, Enterobacter*, and *Serratia* can grow in lactated Ringer's solutions.[5] Microbial growth, with the exception of *Candida* species, is possible in 0.9 percent sodium chloride.[34]

Fungi such as *C. albicans* and *C. glabrata* can grow in PN fluids, albeit very slowly; proliferation did not occur when solutions were stored at 4°C for 7 days.[35] The growth of most bacteria is inhibited in PN solutions. The addition of albumin to PN solutions increases the potential for bacterial and fungal growth.[35] *S. aureus, E. coli, E. cloacae, P. aeruginosa*, and *C. albicans* grow in 10 percent fat emulsion solution.[36,37,38] *Staphylococcus epidermidis, C. albicans*, and *E. coli* survive in total nutrient admixtures (TNAs) in which fat emulsion is combined with dextrose and amino acid mixtures.[39] *P. aeruginosa, S. aureus, S. epidermidis, Enterococcus faecalis*, and group JK (*Corynebacterium jeikeium*), displayed greater growth in TNAs than in PN fluids.[40]

Propofol supported the growth of *S. aureus, E. faecalis, P. aeruginosa*, and *C. albicans*; for *P. aeruginosa* and *E. faecalis*, a bactericidal period was followed, after 48 hours, by increasing growth.[40] Preparations of midazolam HCl, morphine sulfate, fentanyl citrate, bupivacaine HCl, atracurium besylate, vecuronium bromide, epinephrine, dopamine, dobutamine, norepinephrine, and sodium nitroprusside in normal saline and 5 percent dextrose in water were bactericidal for *S. aureus, E. faecalis, P. aeruginosa*, and *E. coli* and did not support growth of *C. albicans* at room temperature in a period of 48

to 72 hours.[40]Propofol and other lipid-based medication can support rapid bacterial growth at room temperature because of their solution pH (between 7 and 8.5) and high lipid content.

Contamination of other pharmaceutical products has led to infections. Intrinsically contaminated albuterol nebulization solutions have led to an outbreak of *B. cepacia*.[41,42]An outbreak of *B. cepacia*caused by contamination of multidose albuterol vials was linked to poor infection prevention practices, including respiratory therapists carrying vials in their pockets for several days. The pH of some solutions tested was not within the recommended range, and the concentration of preservative fell from baseline after 5 days.[42]Intrinsically contaminated saline solution used for respiratory therapy has caused clusters of *R. pickettii*respiratory tract colonization.[43,44]

Bevacizumab is another drug moiety that seems to have an affinity to certain types of pathogenic microorganisms.

The use of contaminated multidose ophthalmic containers has resulted in *S. marcescens* keratitis[45]and *P. aeruginosa* corneoscleritis[46]; the organisms were cultured from the container but not from the solution itself.[46,47]Bacteria were cultured from 82 of 638 in-use multidose ophthalmic solutions; on the other hand, 81 opened multidose ophthalmic medications were tested, and no contamination was found.[48] Irrigation with a cardioplegic solution contaminated with *E. cloacae*led to an outbreak of sepsis.[49]Intrinsic contamination of a product labeled "adrenal cortex extract"—which is not approved by the U.S. Food and Drug Administration (FDA)—caused a series of cases of *Mycobacterium abscessus* abscesses in patients who received intramuscular injections.[50]Contamination of enteral nutrition has been associated with infections, including septicemia.[51,52,53]Many microorganisms, including Gram-negative bacteria, Gram-positive bacteria, and fungi, can proliferate in enteral nutrition preparations.[51,53,54]Mineral oil used for bathing infants was contaminated with *Listeria monocytogenes*, leading to an outbreak of neonatal listeriosis.[55]

A nationwide recall of alcohol prep pads occurred in 2011 as a result of serious acute bacterial infections and patient deaths caused by *Bacillus cereus* contamination. Although there was suggestive evidence of a temporal association between exposure to the suspect products and the onset of serious bacterial infections, there were no confirmed cases to clearly establish that the products served as the primary source for contamination leading to the clinical infections.[56]

Table 110-1 details the ability of various nutritional and non-nutritional parenteral products to support microbial growth when inoculated. From this information, these solutions are categorized as *no antimicrobial activity*or *inhibit microbial growth*for the different organisms for which there are data available. The products that can proliferate certain microbes or show no significant decline in the number of colonies (less than a 20 percent decline from the initial number at 24 hours) will be considered as having *no antimicrobial activity*. Those that have no increase and show a steady decline in colony-forming units (CFUs) per milliliter (more than a 20 percent decrease from the initial inoculum at 24 hours) will be said to *inhibit microbial growth*. This 24-hour mark was chosen because many reconstituted/compounded parenteral products are given a 24-hour beyond-use date upon preparation.

*Also showed NAA to *E. faecalis*

The susceptibilities of various non-nutritional parenteral drugs, according to the criteria put forward in the methods section, are shown in Table 110-1. Some particularly noteworthy solutions were 5-fluorouracil, busulfan, gemcitabine, oxaliplatin, paciltaxel, pentostatin, streptozocin, and treosulfan. These drugs were very commonly able to rapidly decrease the presence of many—in some cases, all—of the different microbes with which they were initially inoculated.

Table 110-2 illustrates the vulnerabilities of various nutritional parenteral products to contamination. Most of these solutions showed a wide range of susceptibilities to many bacterial and fungal contaminants. *C. albicans*demonstrated an ability to either grow very well or sustain prolonged viability in all the nutritional products.

Modes Of Contamination Of Sterile Pharmaceutical Products And Preparations

Most IV-associated infections result from microbial contamination of the cannula and the cannula wound.[5,11] Poor aseptic technique has been associated with endemics and epidemics. Failure to employ aseptic technique during preparation and administration of propofol combined with inherent properties of this product contributed to extrinsic contamination and resulted in postoperative infections.[22] When combined with poor compliance with hand hygiene, garbing and poor aseptic technique procedures have led to various BSIs. Batch preparation of propofol syringes outside a laminar airflow workbench was associated

with *S. aureus*BSIs. [57]*E. cloacae*septicemia resulted from preparation of heparin infusions in an area not specifically designed for such use. [58]An outbreak of *B. cepacia*sepsis resulted from preparation of heparin infusions for several patients using a single 500-mL bag of dextrose that was stored near a sink.[59]

Preparation of compounded sterile preparations in patient care areas (outside the pharmacy) do not typically use a primary engineering control device (e.g., laminar airflow workbench or biological safety cabinet [BSC]) capable of maintaining International Organization for Standardization (ISO) class 5 (no greater than 100 particles per cubic foot or 3,520 particles per cubic meter) air cleanliness conditions. Individuals mixing compounded sterile preparations (CSPs) outside of pharmacy may not have been trained in the proper technique required for this procedure.

Several epidemics have been traced to use of contaminated single-dose vials (SDVs) and multidose vials (MDVs), including an outbreak of fulminant hepatitis B in a hospital that apparently was caused by contaminated heparin flush solution.[60]Unsafe injection practices, specifically the use of the same syringe but new needles for drawing fluid from a common vial, has led to outbreaks of hepatitis C. [61]Failure to follow proper procedures has also led to an outbreak of hepatitis C from extrinsically contaminated radiopharmaceuticals. [62]Proper technique should always be employed when accessing a common vial. Subcutaneous *Mycobacterium cheloneii*abscesses resulted from contamination of diphtheria-pertussis-tetanus-polio (DPTP) vaccine.[63]Contamination of DPTP vaccine was implicated in two outbreaks of group A streptococcal abscesses. [64]Septic arthritis resulted from intra-articular injections of MDV methylprednisolone contaminated with *B. cepacia*.[65]Contaminated MDVs were the most likely source of outbreaks of HCV infections. [66]Interestingly, these infection prevention lapses occurred primarily in outpatient settings and not inpatient hospital settings.

In 2002, five cases of *Exophiala dermatitidis*infection associated with injectable methylprednisolone acetate were reported to the CDC. [67]*Exophiala*is a rare fungus that caused the death from meningitis in one patient, sacroiliitis in another, and meningitis in three other patients who had received either epidural or intra-articular injections of methylprednisolone compounded at Pharmacy A. Cases occurred as late as 152 days after an injection. The methylprednisolone had been prepared at an independent compounding pharmacy (nonhospital based) later found to have improperly used an autoclave; the pharmacy also lacked written procedures for autoclave preparation, performed no testing for sterility or appropriate checking of quality indicators, and had inadequate clean room practices as outlined in the American Society of Health-System Pharmacists (ASHP) guidelines for pharmacy-prepared products in effect at that time.[68]

Other clusters of infections associated with products prepared by compounding pharmacies include *S. marcescens*from betamethasone, *E.dermatitidis*from methylprednisolone, *B. cepacia*from heparin-vancomycin flush solution, *S. marcescens* from magnesium sulfate*, P. fluorescens*from heparinized sodium chloride flush, *P. aeruginosa*or *B. cepacia*from trypan blue ophthalmic solution, multiple Gram-negative bacilli and endotoxin from cardioplegia solution, *Sphingomonas paucimobilis*from fentanyl, *S. marcescens*from total PN, *Streptococcus mitis*and *Streptococcus oralis*from bevacizumab, *Fusarium incarnatum-equiseti*and *Bipolaris hawaiiensis*from brilliant blue-G and triamcinolone, and *Aspergillus*and*Exserohilum*from methylprednisolone.[2]

The 2012 multistate fungal meningitis outbreak caused by a compounding pharmacy in Massachusetts[69] highlights the impact that poor compliance with federal standard of USP <797> Pharmaceutical Compounding – Sterile Preparations[3] and appropriate attention to aseptic compounding can cause. Some state pharmacy regulations require compliance with USP <797>,[70] so emphasis in those states is more evident. However, many sterile preparations are compounded in areas in health systems outside of pharmacy (such as infusion centers, prescriber offices, and other clinics), where state pharmacy regulations may not apply. USP <797> applies to all persons who prepare CSPs and in all places where CSPs are prepared (e.g., hospitals, nursing units, physicians' offices) and other locations where CSPs are prepared, stored, handled, and transported. The IP can play a key role in championing compliance throughout the health system.

When compounding in large-scale facilities and/or across state boundaries, the U.S. Food and Drug Administration (FDA) may become involved. The ASHP's guide for compounding sterile preparations provides direction concerning traditional compounding, such as that done in a health system for its own patients, and exceeds the general prescriber-pharmacist-single-patient relationship.[71] When the FDA inspects a compounding pharmacy, a public report is available.[72] The inspection report information is valuable to the director of pharmacy, IP, and other health system leaders to evaluate use or potential use of such organizations.

Methods for Preventing Contamination of Compounded Sterile Preparations

The CDC recommends that all parenteral fluids be prepared in the pharmacy using an ISO class 5 primary engineering control (e.g., laminar airflow hood). [73] When preparing hazardous drugs for use in oncology patients in a clinic or outpatient setting, use of a BSC or compounding aseptic containment isolator is required. The Infusion Nurses Society (INS) Standards of Practice recommends that an aseptic compounding program be established and conducted under the direction of the pharmacy.[74]

Since the 1990s, several pharmacy practice documents have been published in hopes of establishing a compounding standard of practice that would be universally adopted and followed when preparing sterile preparations. In 1993, ASHP published a Technical Assistance Bulletin *ASHP Guidelines on Quality Assurance for Pharmacy-Prepared Sterile Products*, with the goal of accurate and sterile pharmacy-prepared CSPs. This document was revised in 2000, and again in 2013.[75]

The objective of USP <797> is

to describe conditions and practices that prevent harm, including death, to patients that could result from (1) microbial contamination (nonsterility), (2) excessive bacterial endotoxins, (3) variability in the intended strength of the correct ingredients that exceed either monograph limits for official articles or 10 percent for nonofficial articles, (4) unintended chemical and physical contaminants, (5) ingredients of inappropriate quality in compounded sterile preparations (CSPs).[3]

The current version of USP <797> was published in June 2008 (*USP 31/NF 26*) and provides minimum practice and quality standards for CSPs based on current scientific information and best practices extrapolated from evidence-based practices.

USP Chapter <797> applies to practitioners beyond pharmacists. Drug manufacturers are regulated under the Federal Food, Drug and Cosmetic Act (FFDCA), which requires compliance with USP standards. Practitioners are primarily regulated by state agencies. Although the drugs compounded by

practitioners may still be adulterated or misbranded under the FFDCA, all other aspects of their practice are controlled by state law.

The FDA is responsible for the enforcement of the FFDCA. Each general chapter of the USP/NF is assigned a number, which appears in brackets along with the chapter name. General chapters numbered <1> to <999> are requirements and official monographs and standards of the USP/NF. General chapters numbered from <1000> to <1999> are informational, and chapters above <2000> apply to nutritional supplements.

According to USP <797> CSPs are classified by five general categories based on risk of microbial contamination to all compounded sterile preparations. [72]They are:

- *Immediate Use*: CSPs prepared outside of an ISO 5 device, which are intended for immediate use
- *Low-Risk Level With 12-Hour Beyond-Use Dating*: CSPs prepared in ISO class 5 air cleanliness conditions in an unclassified segregated compounding area with ambient air
- *Low-RiskLevel*: CSPs prepared in ISO class 5 air cleanliness conditions located within ISO class 7 or 8 buffer areas. The compounding procedure involves simple aseptic manipulations using no more than three commercially available ingredients and not more than two entries into any one final container
- *Medium-Risk Level*: CSPs prepared under batch conditions (multiple individual doses) or CSPs for individual patients using more complex aseptic manipulations (e.g., PN solutions and patient-controlled analgesia) prepared in ISO class 5 air cleanliness conditions in an ISO class 7 or 8 area
- *High-Risk Level*: CSPs prepared from nonsterile ingredients or nonsterile devices or prepared in air quality less than ISO class 5 air cleanliness

Unless CSPs are prepared under the Immediate-Use exclusions detailed in USP Chapter <797>, all CSPs must be (at the minimum) prepared in an ISO class 5 environment, which can be achieved by the use of a primary engineering control (e.g., laminar airflow workbench [LAFW], BSC, or isolators designed for pharmacy compounding). (See Table 110-3).

Table 110-3.Compounded Sterile Preparation Risk Levels[71]

Table 110-3 Compounded Sterile Preparation Risk Levels

Category of CSP	Device Used	Surrounding Room	Limitations	BUD*
Immediate use	None	Ambient air	Simple mixing of no more than three sterile nonhazardous components	1 hour
Low-risk, 12-hour	ISO 5 hood†	Ambient air	Simple mixing of no more than three sterile components	12 hours
Low-risk	ISO 5 hood	ISO 7 clean room‡	Simple mixing of no more than three sterile components	48 hours at room temperature, 14 days under refrigeration, 45 days frozen

Medium-risk	ISO 5 hood	ISO 7 clean room	Mixing of all sterile components	30 hours at room temperature, 9 days under refrigeration, 45 days frozen
High-risk	ISO 5 hood	ISO 7 clean room	Includes any nonsterile component or exceeds the BUDs of other categories	24 hours at room temperature, 3 days under refrigeration, 45 days frozen

*The beyond-use date (BUD) is the time that administration of the CSP must begin following mixing of the CSP.

†ISO 5 hood is a properly certified laminar air flow workbench, BSC, compounding aseptic isolator, or compounding aseptic containment isolator.

‡Some isolators may be certified for use outside a clean room but must meet requirements detailed in USP <797>.

Personnel preparing CSPs are required to perform appropriate hand hygiene procedures and wear garb (hairnet, beard cover [as needed], shoe covers, gown closed at the collar, and knit cuffs and sterile gloves) that generates low amounts of particles. Makeup and nail polish are prohibited.

The rubber stoppers of containers must be wiped or sprayed and wiped with sterile 70 percent alcohol or another effective sterile disinfecting agent used prior to entry. The vial septum is not sterile under the cap and must be properly disinfected prior to use.[76]

Several factors must be considered in assessing the sterility of single-use containers (ampules, SDVs, IV bags, irrigation bottles, etc.) [8]and MDVs.[77]The aseptic technique of individuals likely to enter specific vials is an important factor in determining sterility. The environment in which the vial will be punctured is important.

The USP describes the procedure for testing the effectiveness of preservatives in MDVs (USP Chapter <51> Antimicrobial Effectiveness Testing).[78]The effectiveness of the preservatives is demonstrated by the inhibition of growth of microorganisms that may be introduced from repeatedly withdrawing individual doses during a 28-day test period. Some drug preparations appear to have sterilizing properties, irrespective of the presence of preservatives.[79]

The effects of refrigeration on the bactericidal activity of preservative in MDV should be considered in setting policy. Solutions containing preservatives (phenol, methylparaben, and benzyl) and inoculated with *S. aureus, P. aeruginosa, E. coli*, and*S. marcescens* show persistence of bacteria longer under refrigeration than at room temperature.[80]The number of entries may affect sterility of MDVs; however, there is no practical way to document this. In addition, frequent use may cause vials to be used up more rapidly, thereby actually reducing the risk of infection.

Expiration dates listed on drug dosage forms are established by the manufacturer and appear in the FDA-approved product labeling. When a dosage form is manipulated, including puncturing an MDV or moving an item from the storage conditions listed in the product labeling to a different temperature, a

beyond-use date must be applied if the dosage form will be retained for future use. Setting time limits after first opening SDVs and MDVs can help ensure microbial sterility and chemical stability.[8,77,81]

- Manufacturers' expiration dates apply to stability and sterility of unopened vials.
- The CDC recommends that all single-dose and single-use injectable medications and solutions be dedicated for use on a single patient and entered one time. The CDC recommends use of SDVs whenever possible for compounding of parenteral preparations. In times of critical need, contents from unopened single-dose/single-use vials can be repackaged for multiple patients, but only when performed under conditions that are compliant to USP <797> (e.g., qualified personnel, ISO 5 hood in an ISO 7 clean room, beyond-use dates compliant with USP <797> limits, etc .).
- Pharmacy bulk packages (PBPs) are vials containing many single doses. PBPs include large vials of antibiotics, contrast media, and concentrated electrolytes. They are intended for use in an ISO 5 environment for IV additive services. They are not intended for direct patient use or for use outside of appropriate aseptic environments (i.e., an IV hood). SDVs or PBPs (containers of many injectable single-doses) used in ISO class 5 air cleanliness conditions must be discarded after 6 hours unless otherwise specified by the manufacturer.
- The CDC recommends that MDVs should be dedicated to a single patient whenever possible. If MDVs must be used for more than one patient, they should not be kept or accessed in the immediate patient treatment area (e.g., patient rooms or bays, operating room).
- The CDC recommends refrigerating the MDVs after opening if recommended by the manufacturer, cleaning the rubber diaphragm of the vial with alcohol before inserting a device into the vial, using a sterile device each time a vial is accessed, and avoiding touch contamination of the device before penetrating the rubber diaphragm. The MDV should be discarded when empty, when suspected or visible contamination occurs, or when the manufacturer's stated expiration date is reached. [80]
- USP Chapter <797> requires that an MDV after its first opening be discarded within 28 days in accordance with USP Chapter <51>[78]unless otherwise specified by the manufacturer.
- The temperature of refrigerators used to store pharmaceuticals should be checked daily (twice daily if used to store vaccines) and the temperature recorded electronically or on a log that is dated and signed by the person performing the temperature check. Temperatures that are higher or lower than recommended should be immediately addressed and adjusted as defined in the organization's policy. Refrigerators used in pharmacy or other bulk storage areas such as materials management to store medications in general should have their temperature monitored continuously, with alarms set to indicate excessively high or low temperatures.

USP <797> beyond-use dates apply from the time the CSP is compounded up to the point of administration. Once administration begins, CDC recommendations for hang time applies.

The CDC has not made recommendations for the hang time of general IV fluids, though it makes the following comments.[73]

- Manufacturers' recommendations should be followed for specific medications.
- PN (with or without fat) hang time should not exceed 24 hours.
- Fat emulsion hang time should not exceed 24 hours.
  - The INS Standards limit fat emulsion hang time to 12 hours.[74]

- Propofol infusion hang time should not exceed the manufacturer's recommendations (which vary based on manufacturer) and should be changed at the same time as the tubing.

The CDC also lists recommendations for IV tubing changes:[73]

- In patients not receiving blood, blood products or fat emulsions, replace administration sets that are continuously used, including secondary sets and add-on devices, no more frequently than at 96-hour intervals but at least every 7 days.
- Replace tubing used to administer blood, blood products, or fat emulsions within 24 hours of initiating the infusion.
- Replace tubing used to administer propofol infusions every 6 or 12 hours, when the vial is changed, per the manufacturer's recommendations.

Environmental Sampling and Testing

Environmental monitoring is approached differently by the CDC, FDA, and USP. The FDA requires manufacturers to have a comprehensive environmental monitoring plan that involves daily sampling of air, surfaces, and personnel with baseline CFU levels for alert and action levels.[82]

In the 1970s, the CDC began to advocate the discontinuation of environmental monitoring in the hospital because there was no association between infection rates and levels of environmental contamination and because there were no standards for permissible levels of environmental microbial contamination. The issue of routine microbiologic sampling of the environment in healthcare facilities is specifically addressed in the evidence-based document *Guidelines for Environmental Infection Control in Healthcare Facilities—2003*.[83]The CDC environmental guidelines specifically recommend against environmental sampling in all practice settings within the hospital unless part of an investigation, education, or equipment certification.

The USP historical model for environmental monitoring in the clean room is based on a pharmaceutical manufacturing model of routine sampling recommended by the FDA. The emphasis on environmental air quality originates from early studies demonstrating the lack of microbial contamination when sterile drugs, nutrients, and devices were handled and aseptically prepared in controlled environments where the air cleanliness classifications were controlled.[81'84,85,86]

Based on the CDC and FDA position, the current USP Chapter <797> on pharmaceutical compounding, environmental sampling is recommended as part of a comprehensive quality management program and required under any of the following conditions:

- As part of the commissioning and certification of new facilities and equipment
- Any servicing of facilities and equipment
- As part of the semiannual recertification of facilities and equipment
- In response to identified problems with end products or staff technique
- In response to issues with CSPs, observed compounding personnel work practices, or patient-related infections where the CSP is being considered as a potential source of the infection[3]

The current air, surface, and personnel gloved fingertip sampling requirements in USP Chapter <797> have been broken down into facility-associated environmental sampling and personnel-associated sampling. Environmental sampling is one important quality assurance procedure required of all

compounders (pharmacists, technicians, nurses, physicians, and others) and should be tied to activities that pose the greatest risk of contamination to the compounded sterile preparation, such as hand hygiene, garbing and gloving, cleaning, and aseptic compounding procedures.

Each individual who compounds sterile preparations for other than Immediate Use must successfully pass a simulated media fill test (to demonstrate compliance with aseptic compounding practices), a gloved fingertip test (to demonstrate compliance with the ability to aseptically garb), and surface sampling test (to demonstrate the ability to properly clean sterile compounding areas, as well as assure use of effective cleaning solutions and dilutions). The frequency of testing varies depending on the type of CSPs mixed and is detailed in USP <797>.[3]Those individuals (such as nurses and anesthesia personnel) who prepare Immediate-Use CSPs must document competency in aseptic technique and organizational policy.

The frequency of environmental sampling, as well as the methods and materials used to collect the samples, have been harmonized with the recommendations of the American Society of Microbiology. [87]

The goal is to ensure that the ISO-classified compounding areas are working properly and are maintaining a state of control relative to the number of airborne nondiscrete particles. The primary engineering controls (laminar airflow workbenches or zones, BSCs, or isolators), which provide unidirectional airflow, are used for all compounding activities, except in emergencies. The buffer area (ISO class 7) and ante area (ISO class 8) must be designed and built to meet the architectural and performance criteria stipulated in USP <797>. Certification procedures such as those outlined in *Certification Guide for Sterile Compounding Facilities*(CAG-003-2006)[88]shall be performed by a qualified individual no less than every 6 months and whenever the device is relocated or altered or a major service occurs.[3]

USP <797> lists recommended action levels for microbial growth.[3]When microbial growth is detected, isolates must be identified to at least the genus level, and appropriate action must be taken.

Aseptic Technique

Based on a review of published literature for the rates of contamination of aseptic media fills in pharmacy settings and two industrial pharmaceutical manufacturer surveys (the first in 1986 and the last in 2001), direct contact (i.e., touch contamination) by compounding personnel poses the highest risk of microbial contaminations of CSPs.[81,84,85,89,90,91,92,93,94,95]"It is dangerous to assume that the use of a clean room will independently improve the quality of patient care by eliminating contamination. Once a baseline environmental quality (ISO class 5 LAFW) is established, admixture quality assurance efforts should focus on other critical factors." [84]Personnel are the greatest source of microbial contamination in industrial aseptic manufacturing, which is attributed to touching and particle shedding.[85]

Recent studies involving medical procedures that require aseptic technique while working in uncontrolled air environments (e.g., patient care units and surgical suites) have demonstrated the incidence of extrinsic contamination and the critical nature of using proper aseptic technique and standard practices to prevent infections.[96,97,98,99]

Storage of Pharmaceuticals

The pharmacy should monitor for appropriate storage of pharmaceuticals throughout the institution. Routine inspections should be performed to ensure that expired medications are removed from patient

care areas and disposed of properly. Temperatures of refrigerators, freezers, and warmers used to store pharmaceuticals should be closely monitored and recorded daily.

Pharmacist Responsibilities Involving Antimicrobial Stewardship

Concerns about resistance causing increased morbidity, mortality, and healthcare costs have led to recommendations to control antimicrobial use.[100,101] Multidisciplinary groups, including physicians, nurses, pharmacists, laboratory technicians, respiratory therapists, and others, should establish a system for monitoring resistance and antibiotic usage, establish evidence-based practice guidelines and other policies to control the use of antibiotics and respond to data from the monitoring system, and measure outcomes to evaluate the effectiveness of policies. Microbiologists should work with infectious disease clinicians, pharmacists, hospital epidemiologists, IPs, and representatives of clinical departments to choose the drugs that will be tested and routinely reported. Specific responsibilities for pharmacy personnel include promoting optimal use of antimicrobial agents, generation and analysis of data to determine compliance with restriction policies, participation in development of programs for formulary and antimicrobial controls, responsibility for computer medication order entry systems and protocols, and (in collaboration with physicians) patient-specific recommendations for optimal antimicrobial use.[97,102,103,104,105,106,107,108]

Pharmacist Participation in Infection Prevention and Control Committee

Pharmacy services should be active participants in the organization's infection prevention and control committee. The committee should review the quality plan elements of pharmacy service's sterile compounding activities, including personnel training and competence, facility issue, and environmental monitoring. Antibiotic stewardship activities should be discussed at the committee.

Infection Preventionist Partnership with the Pharmacy

The IP can provide subject matter expertise to the pharmacy director when it comes to appropriate cleaning and disinfection practices, hand hygiene, environmental sampling, adult education on aseptic technique and other infection control-related topics, proper donning and removal of personal protective equipment, and should participate in regularly scheduled environment of care rounds. The IP can also assist with a gap analysis/risk assessment of various pharmacy practices that ultimately affect patient safety.

The IP should be immediately consulted when a suspected or confirmed contamination event has been identified. Coordination with Department of Health authorities along with State Board of Pharmacy is essential, and it should involve collaboration with the IP and pharmacist, as well as active engagement of the healthcare facility administration to maximize patient safety. The IP is an integral member of the antibiotic stewardship team and has ongoing responsibility for performing surveillance of patients colonized or infected with MDROs. The CDC recently published a monograph on antibiotic resistance threats in the United States that identified certain organisms as threats to human health. The CDC classified these organisms as "urgent," "serious," or "concerning":[109]

Urgent Threats

- *Clostridium difficile*
- Carbapenem-resistant Enterobacteriaceae (CRE)
- Drug-resistant *Neisseria gonorrhoeae*

Serious Threats

- Multidrug-resistant *Acinetobacter*
- Drug-resistant *Campylobacter*
- Fluconazole-resistant *Candida*(a fungus)
- Extended spectrum β-lactamase producing Enterobacteriaceae (ESBLs)
- Vancomycin-resistant *Enterococcus*(VRE)
- Multidrug-resistant *Pseudomonas aeruginosa*
- Drug-resistant non-typhoidal *Salmonella*
- Drug-resistant *Salmonella Typhi*
- Drug-resistant *Shigella*
- Methicillin-resistant *Staphylococcus aureus*(MRSA)
- Drug-resistant *Streptococcus pneumoniae*
- Drug-resistant tuberculosis

Concerning Threats

- Vancomycin-resistant *Staphylococcus aureus*(VRSA)
- Erythromycin-resistant Group A *Streptococcus*
- Clindamycin-resistant Group B *Streptococcus*

Conclusions

Pharmacy is responsible for preparation and storage of most sterile medications. The pharmacy department should participate in multidisciplinary activities such as quality assurance teams, infection prevention and control committees, and antimicrobial use programs to ensure appropriate preparation and use of pharmaceuticals and sterile products. Recently, Pronovost et al.[97]demonstrated that the application of the five evidence-based procedures recommended by the CDC had the greatest effect on lowering the rate of catheter-associated BSIs. They also demonstrated the lowest barriers to implementation with sustained positive impact on patient outcomes. Such strategies of bundling best practices that are evidence based, observational assessments for compliance, and use of checklists as reminder tools to standardize processes are as relevant to the pharmacy as they are to the clinician caring for the patient at the bedside. The challenge remains to create a culture of patient safety that rewards team building, eliminates hierarchy, and promotes speaking up when potential human error is recognized.

Future Trends

Many of the tools that the IP is using to improve patient care at the bedside can be easily adapted to assist the pharmacist in ongoing efforts to ensure enhanced patient safety. The use of observational tools and checklists is just one way the IP can team with the pharmacist to improve the safety of medication preparation and delivery within healthcare facilities. Future opportunities for such collaboration will likely continue and expand across the spectrum of healthcare.

International Perspective

The profession of pharmacy both in the United States and around the world is experiencing a renaissance regarding the roles of pharmacists in the delivery of healthcare in the 21st century. By moving out of isolation and expanding their traditional roles, which historically have revolved around medication delivery and distribution only, pharmacists are being greeted by teams of healthcare professionals realizing the important role they play in delivering evidence-based, patient-centered care.

IPs are realizing that the pharmacy and the sterile compounding of medications/preparations may be more problem-prone than originally thought and a potential sourc e of HAIs. The opportunity for pharmacists and IPs to work collaboratively is apparent, with the goal of eliminating the ongoing threats to the patient from contaminated medications/preparations while being treated in healthcare facilities.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Healthcare Textile Services

Author(s): Carol McLay, DrPH, BSN, RN, CIC
Infection Prevention Consultant

Lexington, KY

Published: March 10, 2016

Revised: March 10, 2016

Abstract

Healthcare textiles are fabric products that touch patients and employees directly or indirectly on a daily basis. Contaminated textiles in healthcare facilities are known to be a source of substantial numbers of pathogenic microorganisms. However, adherence to the U.S. Centers for Disease Control and Prevention (CDC) Guidelines for Environmental Infection Control [1] and compliance with the mandated requirements in the Occupational Standards and Health Administration (OSHA) Bloodborne Pathogens Standard [2] are effective in keeping the risk of actual disease transmission to patients and healthcare workers (HCWs) negligible. This exemplifies the importance of the entire laundering process to render textiles safe and suitable for reuse. The key elements in the laundering process include water temperature, type of detergents, disinfectant (i.e., sodium hypochlorite [chlorine bleach]), rinsing, and finishing. The process is supplemented by common sense and hygienic approaches to collection and transport. The use of a defined and effective laundering process, the parameters of which are established in the industry, is essential for the production of hygienically clean textiles.

Key Concepts

- Hygienically clean laundry carries negligible risk to healthcare workers and patients, provided that the clean textiles, fabric, and clothing are not inadvertently contaminated before use.
- Complying with CDC environmental guidelines and OSHA rules on bloodborne pathogens is highly effective in protecting against disease transmission through textiles.
- Efforts to reduce the occupational risk of infection associated with handling contaminated textiles should primarily focus on the appropriate use of hand hygiene, protective barriers, and removal of foreign objects from the contaminated textile product stream.

- The role of healthcare workers' attire in the transmission of bacteria and development of healthcare-associated infections is not clear. The Association of periOperative Registered Nurses (AORN) recommends that all perioperative personnel should wear freshly laundered surgical attire that is laundered at a healthcare-accredited laundry facility or disposable surgical attire.
- Linen teams with key representatives from both organizations including infection preventionists should be created to develop standards and policies regarding linen use and processing, and to address continuous improvement.
- There is a rapidly growing demand for antimicrobial textiles in the healthcare sector.
- Voluntary accreditation and certification programs are available to demonstrate compliance with regulatory standards and industry best practices.
- Healthcare laundries are an integral component of the multidisciplinary team approach necessary to improve patient outcomes.

Background

Although contaminated textiles and fabrics in healthcare facilities can be a source of substantial numbers of pathogenic microorganisms, the CDC states that reports of healthcare-associated diseases linked to contaminated fabrics are so few in number that the overall risk of disease transmission during the laundry process likely is negligible. [1,3] Those infections thought to be occupationally acquired were frequently the result of improper handling of these textiles (i.e., the shaking of soiled linens). Efforts to reduce the occupational risk of infection associated with handling contaminated patient care and/or surgical textiles should primarily focus on the appropriate use of hand washing, protective barriers, and removal of foreign objects from the contaminated textile product stream. [4] Bacteria (*Salmonella spp*., *Bacillus cereus*), viruses (hepatitis B virus [HBV]), fungi (*Microsporum canis*), and scabies presumably have been transmitted from contaminated textiles and fabrics to employees by direct contact or via aerosols of contaminated lint generated from sorting and handling contaminated textiles. On further investigation, presumed occupational infections associated with textile handling were often found to be community acquired. Outbreaks of infectious diseases associated with laundered textiles are rare; during the past 43 years there have been 12 reported cases globally. To date, there have been no published reports of patient-to-patient transmission of infection associated with hygienically clean textiles (HCT). [3]

The provision of HCT is essential and rigorous standards must be followed during all phases of the healthcare laundry process to reduce the risk of infection and ensure patient safety. Comprehensive innovations in textile cleaning and processing, service, and disinfection now enable healthcare facilities and their commercial laundry partners to provide high-quality textile products that carry negligible risk of infection for patients.

Key Terms and Definitions

Antimicrobial fabric: Antimicrobial fabrics and textiles are fiber-based substrates to which antimicrobial agents have been applied at the surface, or incorporated into the fibers, rendering a product that kills or inhibits the growth of microorganisms.

Cleaning: A process that uses a cleaning agent and physical action, such as scrubbing or wiping, to removed visible soil, organic matter, and bioburden from a surface or object and in doing so renders the surface of object safe to handle. The cleaning agent may be a wet or dry chemical. The specifics of a

cleaning process are dictated by factors associated with the item to be cleaned, namely chemical compatibility, location, wetness tolerance, surface topography and complexity.

Condition/drying area: An area where, after extraction, textiles are either conditioned (partly dried) or fully dried in a dryer or tumbler.

Contaminated: The presence of blood or other potentially infectious material (OPIM) on an item or surface.

Contaminated Laundry: According to the Occupational Safety and Health Administration (OSHA), laundry that has been soiled with blood or OPIM, or may contain sharps.

Decontamination: The use of physical or chemical means to remove, inactivate, or destroy bloodborne pathogens on a surface or disinfecting the item to the point where it is no longer capable of transmitting infectious particles and the surface or item is rendered safe for handling, use, or disposal.

Extraction area: An area where excess water is removed from textiles after laundering, but before conditioning or drying.

Folding area: An area where textiles are folded.

Foreign object: Objects or items considered as non-textile items (e.g., instruments, disposable devices, sharps, personal patient information, etc.) that may potentially harm people and laundry equipment if left among the textiles.

Functional separation/barrier: An activity or structure that separates one movement, action, or space from another. Examples include structures such as walls or partitions, carts, and ventilation parameters such as airflow directions and pressure. Functional separation achieved through ventilation usually employs negative air pressure to prevent potential pathogens from spreading to other areas in the facility.

Personal Protective Equipment: Specialized clothing or equipment worn by an employee for protection against a hazard. General work clothes (e.g., uniforms, pants, shirts, or blouses) not intended to function as protection against a hazard are not considered to be PPE. Where there is occupational exposure, the employer shall provide and maintain, at no cost to the employee, appropriate PPE such as but not limited to gloves, gowns, laboratory coats, face shields or masks, and eye protection.

Hygienically clean: A clean state, free of pathogens in sufficient numbers to minimize risk of infection.

Processed: Terminology that describes items that have been laundered, cleaned, disinfected, or sterilized as appropriate for safe use in an intended activity.

Receiving area: An area where soiled textiles are sorted, usually by textile category and sometimes by degree of soiling or color.

Staging: A process for preparing the textiles for delivery and having them wrapped and ready for transport.

Other Potentially Infectious Material (OPIM): The following human body fluids: semen, vaginal secretions, cerebrospinal fluid, synovial fluid, pleural fluid, pericardial fluid, peritoneal fluid, amniotic fluid, saliva in dental procedures, body fluid that is visibly contaminated with blood, and all body fluids in situations where it is difficult or impossible to differente between body fluids: any unfixed tissue or organ (other than intact skin) from a human (living or dead); HIV-containing cell or tissue cultures, organ

cultures, and HIV- or HBV- containing culture medium or other solutions; and blood, organs, or other tissues from experimental animals infected with HIV and HBV.

Soiled: Describes a textile product that has been used or worn and soiled by perspiration, body oils, or one of the many other items to which it may have been exposed.

Standard Precautions: The CDC term/isolation category that incorporates Universal Precautions and Body Substance Precautions and includes a group of infection prevention practices that apply to ALL patients regardless of suspected or confirmed infection status in any setting where healthcare is delivered.

*Universal Precautions: A*n approach to infection prevention that considers all textile products being sent to the laundry as being contaminated. *Special note*: Under these circumstances, it is not necessary to identify the bags in which the textiles are transported in any special manner, because they will all be handled/laundered the same way.

Washing (processing) area: An area where soiled textiles are washed and in which such equipment as washers, extractors, washer-extractors, continuous-batch washers and/or continuous processing systems is located; also known as the wash floor.

Basic Principles

Laundry services play a critical role in a healthcare facility's infection prevention and control program. Healthcare textiles include bed sheets, pillowcases, blankets, towels, personal clothing, patient apparel, employee uniforms, scrub suits, gowns, and drapes for surgical procedures.Contaminated textiles often contain large numbers of microorganisms from body substances such as blood, skin, stool, urine, vomitus, and other body tissues and fluids, and it is important to ensure that pathogens are not transferred to patients or healthcare workers.

Organisms commonly found on healthcare textiles include gram-negative bacteria, coagulase negative staphylococci, and *Bacillus* sp. in addition to normal microbial skin flora. [5,6]

Reports on the survival of microorganisms on hospital textiles after laundering are diverse and based on a variety of different laundry temperatures and processes. In their literature review, Fijan et al. (2012) summarized data on the persistence of pathogens on hospital textiles. Laundering conditions in the published literature were variable with temperatures ranging from 22.2° C to 77.2° C using a variety of disinfectants. Surviving microorganisms in these studies included *Enterococcus faecium, Enterococcus faecalis, Staphylococcus aureus, Pseudomonas* and *Klebsiella* species, as well as *Clostridium difficile* spores. In addition to bacteria, molds and viruses including rotavirus and parainfluenza virus have been cultured from hospital textiles. [5]

Bacteria (*Salmonella spp*., *Bacillus cereus*), viruses (hepatitis B virus [HBV]), fungi (*Microsporum canis*), and scabies presumably have been transmitted from contaminated textiles and fabrics to employees by direct contact or via aerosols of contaminated lint generated from sorting and handling contaminated textiles. On further investigation, presumed occupational infections associated with textile handling were often found to be community acquired. [1,5,6]

Some investigators have examined the connection between healthcare textiles and infectious disease outbreaks and their conclusions emphasize that fact that correct laundering of healthcare textiles is an

important measure for preventing healthcare-associated infections (HAIs).

Several *Bacillus cereus* nosocomial infections in Japan were investigated and novel multilocus sequence types were found in patients. *B. cereus* contamination was observed with reusable (dried and steamed) towels and washing machines in hospital linen rooms. The authors speculated that contamination of the towels occurred in washing machines in the hospital linen room. When towels were treated with sodium hypochlorite and then laundered by an external cleaning company, no further contamination was detected. [7]

In another investigation of a *Bacillus cereus* bacteremia outbreak, hospital linens and the hospital washing machine were highly contaminated with *B. cereus*, which was also isolated from the intravenous fluid of symptomatic patients. All of the contaminated linens were autoclaved, the washing machine was cleaned with a detergent, and improved hand hygiene was promoted among the hospital staff. These measures successfully terminated the transmission of infection. The source of this outbreak was identified as *B. cereus* contamination of hospital linens, and the authors theorized that *B. cereus* was being transmitted from the linens to patients via catheter infection. The linens had been washed in the hospital washing machine, which reused water for washing and rinsing. Furthermore, the machine had not been cleaned for over 10 years. [8]

In 2010, the CDC presented a paper on its investigation of an outbreak of zygomycosis, a fungal-based infection that can be potentially life-threatening to patients with weakened or compromised immune systems. Hospital textiles were identified as the only common element among all the cases. Environmental sampling performed at the hospital on the textiles and areas in contact with textiles revealed a 40% presence of the pathogen, and only a 4% presence in items and areas not in contact with textiles. The facility changed its laundry provider, replaced all of its linen, and disinfected the linen storage areas. Cultures taken at the hospital three weeks later were all negative. The authors concluded that hospital linens likely acted as a vector bringing Rhizopus in contact with susceptible patients in this outbreak. Rhizopus might have contaminated linens at the laundry facility or during delivery to the hospital. The CDC recommends that hospital linens should be laundered, shipped, and stored in a manner that minimizes exposure to environmental contaminants. [9]

An outbreak of *Bacillus* species bacteremia was reported among critically ill premature infants in a neonatal intensive care unit (NICU) during a hospital expansion construction project. Cultures from several NICU workstations, the respiratory therapy workstation, and the storage room as well as hospital linens grew *Bacillus* species. The outbreak task force speculated that contamination of linens could have been a factor contributing to the outbreak since items were delivered to the loading dock adjacent to the excavation site. [10]

Through a combination of soil removal, pathogen removal, and pathogen inactivation, contaminated laundry can be rendered hygienically clean. Hygienically clean laundry carries negligible risk to healthcare workers and patients, provided that the clean textiles, fabric, and clothing are not inadvertently contaminated before use. The laundering process consists of the proper combination of water, heat, pH, oxidation, chemical sanitizers, and drying and sanitizing. Additional factors that play a vital role in ensuring hygienically clean textiles include the physical layout of the laundry and the design of the facility infrastructure.

The Laundry Service

It is estimated that 10 billion pounds of heathcare-setting textiles are processed annually. [11] Healthcare laundry is generally processed by a facility's own laundry (on-premise laundry, external hospital-owned facility, or shared laundry service), or outsourced to a commercial, retail facility with customer-owned goods or laundry facility-provided textiles. Facilities are increasingly turning to outsourcing to offset the risk and costs associated with managing textiles in-house. Laundry services are in fact the most outsourced hospital department contract. [11]

Laundry facilities that place surgical textiles (whether sterile or nonsterile) into commercial distribution come under the jurisdiction of Food and Drug Administration (FDA) regulations. In addition, laundry facilities may be subject to local and state regulations as well as Environmental Protection Agency (EPA) and Occupational Safety and Health Administration (OSHA) requirements.

To be eligible for reimbursement, hospitals must be compliant with the Federal Medicare Conditions of Participation (CoPs). The CoPs contain the minimum health and safety requirements that hospitals must meet. According to the CoPs, the hospital's governing body is responsible for oversight of contracted services. The governing body must ensure that a contractor furnishes services in a manner consistent with acceptable standards of practice. Hospital personnel should conduct an on-site inspection at least annually to ensure compliance to standards. These conditions are driving the current movement toward using accredited or certified healthcare laundries. Many healthcare facilities have created linen teams with key representatives from both organizations to develop standards and polices regarding linen use and processing, and to address continuous improvement.

Accredited healthcare laundries are compliant with the standards promoted by the Healthcare Laundry Accreditation Council (HLAC), a non-profit organization formed for the purpose of inspecting and accrediting laundries processing healthcare textiles for hospitals, nursing homes, and other healthcare facilities. HLAC's mission is to publish high standards for processing healthcare textiles in laundries, and provide an inspection and accreditation process that recognizes those laundries that meet these standards. The HLAC Accreditation Standards (revised 2016) are established as the minimum acceptable practice for the preparation of hygienically clean, reusable healthcare textiles for patient care, implemented and executed by accredited laundry facilities processing reusable healthcare textiles. [12] The document covers the complete textile processing cycle: from handling and transporting to laundering and finishing to customer service. The standards incorporate evidence-based, peer-reviewed best practices and recommendations for infection prevention and laundry procedures from federal agencies (e.g., Centers for Disease Control and Prevention (CDC)) and professional entities such as the American National Standards Institute (ANSI), the Association for the Advancement of Medical Instrumentation (AAMI), Association of periOperative Registered Nurses (AORN), the Association for Professionals in Infection Control and Epidemiology (APIC), Facilities Guidelines Institute (FGI), and the Textile Rental Services Association of America (TRSA).

AORN has awarded its AORN Seal of Recognition to the 2016 HLAC Accreditation Standards, which confirms that the content of the document has undergone thorough review by AORN and meets the guidelines of the "AORN PeriOperative Standards and Recommended Practices."

The standards consist of three sections:

Part I Basic Elements includes such topics as laundry facilities, equipment, personnel, and quality assessment. Mandatory requirements include:

- A functional barrier by negative air pressure in soiled areas

- Warning signs about the presence of contaminated textiles and the need to follow Universal Precautions must be posted in work areas.
- The textile areas must be free of vermin, devoid of lint, and without obvious moisture contamination.
- Cardboard must not be used as shelf liner material.
- Hand hygiene resources must be available in or around all work areas and in personnel support areas.
- Emergency eyewash/shower equipment must be available with unobstructed access.
- Safety features (e.g., emergency lighting, signage, fire alarms, door accessibility and egress, safety perimeter for robotics, equipment guards) must be evident and operational.
- Working surfaces must be kept clean of visible soil, dust, and lint.
- Working surfaces that become contaminated with blood or OPIM must be decontaminated, cleaned, and disinfected with EPA-registered hospital disinfectants labeled tuberculocidal or registered disinfectants on the EPA Lists D and/or E.
- A written Regulated Medical Waste management plan
- Compliance with regulations as they pertain to air, water, and chemicals management
- Evidence of waste water and/or air quality permit compliance
- Compliance with hazardous chemical regulations
- Documentation on types of laundry equipment, equipment installation, operation, safety, preventative maintenance, and repairs
- Descriptions of personnel qualifications and responsibilities
- Documentation of personnel health and hygiene and use of PPE and attire
- An occupational safety and health program based on the OSHA Bloodborne Pathogen Standard and Universal Precautions
- An Exposure Control Plan (ECP)
- A hepatitis B vaccination program
- A standing process for post-exposure management for blood and/or OPIM
- A hazardous materials (e.g., non-biological, chemical, radiological) safety plan and policy
- Training and educational programs must include Bloodborne Pathogens Exposure Control Training, Hazardous Substance Contaminated Textiles training, Department of Transportation (DOT) regulations training

Part II includes seven subsections on the textile processing cycle. Pertinent requirements include:

Handling, Collection and Transportation of Soiled Healthcare Textiles

- Healthcare textiles must be handled and collected in accordance with OSHA regulations and federal guidelines, thereby minimizing potential exposure of patients, hospital personnel, or laundry personnel to bloodborne pathogens or other infectious agents.
- Soiled healthcare textiles must be assumed to be contaminated; personnel who handle soiled textiles must follow Standard Precautions at all times.
- Soiled textiles shall be collected and handled only as necessary to complete the defined tasks, and in such a way as to minimize microbial contamination of the air and the personnel handling the textiles. Soiled textiles must not be sorted or rinsed in patient-care areas.

- The collection bags or containers must functionally contain wet or soiled textiles and prevent contamination of the environment during collection, transportation, and storage prior to processing. The containers must not tear when loaded to capacity, be leak-proof, and be capable of being closed securely to prevent textiles from falling out.
- The bags or other containers must be color-coded or labeled. If only soiled healthcare textiles are coming into the laundry, and all personnel are following standard precautions when handling these textiles, the bags do not need to be color-coded or labeled.
- The laundry provider must maintain functional separation of clean from soiled textiles in carts and/or vehicles at all times during the collection and transportation of soiled textiles.
- Standard precautions must be observed while moving, loading, and unloading soiled textiles.

Washing, Extraction and Drying

- The wash process shall ensure that healthcare textiles become hygienically clean.
- Three basic types of washing equipment are used in the processing of healthcare textiles: washers, washer/extractors, and continuous batch washers. Depending on the type of equipment in use, modifications in these requirements and other factors affecting the process may be necessary to ensure that quality standards are consistently met. If modifications are necessary, they shall be documented, dated and revised as needed.
- The load size (weight) for each classification of soil shall be established by the facility and recorded for each load processed.
- The wash cycle shall comply with all applicable state and local requirements for healthcare textile processing.
- Each classification shall have established standards for the following factors: Cycle time: Pre-wash, wash, rinse, and final rinse times; water levels/usage (total water usage and/or water levels); temperature (wash cycle, bleach cycle and rinse cycle temperatures); and chemical usage (chemical types and usage levels for each step in the wash process).
- Clean healthcare textiles shall be extracted or dried in a manner that preserves the integrity of the textile merchandise, minimizes microbial growth after washing, and prepares the textiles for efficient ironing or folding. Damp textiles shall not be left in machines overnight.

Finishing

- The finishing process of ironing or folding textiles shall ensure that the merchandise is maintained in the same clean state that it emerged from washing.
- The ironing or folding procedures shall meet the needs and expectations of the user. If any textiles become soiled in this process, they shall be rewashed.
- Ironing equipment shall be maintained in good operating condition so that it adequately irons, dries, and folds the textiles without excessive heat, pressure, or mechanical damage. The equipment shall maintain a temperature of at least 300 degrees on the ironer chests.
- Dry folding equipment shall be in good operating condition.

Packaging and Storing

- Packaging and storage of healthcare merchandise shall maintain the textiles in a clean state for delivery to the customer.

- The textiles may be wrapped into fluid-resistant bundles, or placed bundled but unwrapped into fluid-resistant covered carts or hampers. The wrapping material may be plastic or other suitable material, and shall be securely closed during transport to the customer.
- During packaging, textiles shall be handled as little as possible to prevent soiling or contamination.
- If unwrapped merchandise is placed into carts or hampers and covered, the container shall remain covered at all times until delivered to the user's textiles storage room or other designated location in the healthcare facility. If the cart does not have a solid bottom, it must be lined with heavy plastic or impervious paper before placing clean textiles inside.
- Bundled and wrapped textiles may be stored in open racks in the laundry, on the trucks, or at the user's facility, provided the integrity of bundled and wrapped textiles is not compromised.
- Unwrapped clean textiles may be stored in designated rooms.
- The laundry storage room shall only be accessible to appropriate personnel.
- Only clean linens shall be stored in this area and signage posted as "Linen storage room."
- The door shall remain closed at all times.
- If any textiles become soiled during packaging and storage, they shall be reprocessed in accordance with previously stated processing guidelines.

Delivery of Cleaned Healthcare Textiles

- Maintain functional separation of clean from soiled textiles during transportation by bagging soiled textiles in fluid-resistant containers and anchoring soiled textiles in the vehicle so that they do not spill from their containers.
- Clean and soiled textiles may be transported in the same vehicle if functional separation is maintained using physical barriers, and/or space separation sufficient to protect clean textiles from contact with soiled textiles.
- Train personnel regarding proper bagging and placement of textiles in the transporting truck; ensure that all employees follow standard precautions at all times.
- Clean and soiled textiles shall not be stored in the same container.
- If a cart is used to transport clean textiles, the textiles shall be wrapped inside the car, or if unwrapped, the cart shall be lined with plastic or heavy paper and covered. Carts must be maintained in good working order.
- Carts, containers, covers, and liners used to collect or transport soiled textiles must be properly cleaned and disinfected after the cart is emptied and before any next use, whether to transport clean textiles or soiled textiles.
- The interior of the transport vehicle shall be cleaned on a regular basis or when visibly soiled.
- Vehicles must have waterless hand cleaner, PPE, and spill kits on board.

(Part III addresses Surgical Pack Assembly Room Standards, details of which will not be covered in this chapter.)

The Laundering Process

The laundering process is designed to produce healthcare textiles that are free of vegetative pathogens (hygienically clean). Laundering cycles consist of flush, main wash, bleaching, rinsing, and souring. Cleaned wet textiles are then dried, pressed, and prepared for distribution back to the healthcare facility.

According to the CDC (2003), the antimicrobial action of the laundering process results from a combination of mechanical, thermal, and chemical factors. [1] Substantial numbers of microorganisms are removed through the process of dilution and agitation. Soaps and detergents function to suspend soil and exert microbiocidal properties. Hot water also provides an effective means of destroying organisms. A temperature of at least 160° F (71° C) for a minimum of 25 minutes is recommended for hot-water washing. [1] Alternatively, low temperature washing at 71°F to 77°F (22°C - 25°C) can reduce microbial contamination when the wash cycle duration, detergent, and amount of laundry additive are monitored and controlled. [13] The selection of hot or cold water laundry cycles may be dictated by state licensing or other standards. The cleansing action is followed by a number of cycles, such as one for the chlorine bleach, a series of rinses, and finally the sour step, which neutralizes any residue of the chemicals that were used. Chlorine bleach is an economical broad-spectrum germicide but it may not be appropriate for all fabrics. Chlorine alternatives (e.g., activated oxygen-based detergents) may be used to ensure adequate disinfection of laundry. Dryer temperatures and cycle times are dictated by the materials in the fabrics. Regardless of whether hot or cold water is used in the wash process, the temperatures reached in drying and ironing provide additional microbicidal action and reduce the microbial load to an insignificant amount. When textiles are laundered using proper amounts of each chemical and subjected to adequate dilution, mechanical action, and water temperatures, the patient is ensured of being provided items that are “hygienically clean.”

Recent improvements in technology utilized in laundry processing have been recognized by the Centers for Medicare & Medicaid Services (CMS). In January 2013, CMS [13] clarified and revised the agency’s guidance for F Tag 441 on the following components of the laundry process:

Laundry detergents: Modern-day detergents are much more effective in removing soil and reducing the presence of microbes. The CMS in collaboration with the CDC has determined that facilities may use any detergents designated for laundry in laundry processing. Further, laundry detergents used within nursing homes are not required to have stated anti-microbial claims.

Water temperatures and chlorine bleach rinses: The chlorine bleach rinse is not required for all laundry items processed in low temperature washing environments due to the availability of modern laundry detergents that are able to produce hygienically clean laundry without the presence of chlorine bleach.

Maintenance of equipment and laundry items: Facilities are not required to maintain a record of water temperatures during laundry processing cycles. The CDC recommends leaving washing machines open to air when not in use to allow the machine to dry completely and to prevent growth of microorganisms in wet, potentially warm environments. Facilities are required to follow manufacturer’s instructions for washing machines, dryers, detergents, rinse aids, and other additives.

Ozone cleaning systems: The CMS in collaboration with the CDC has determined that ozone cleaning systems are acceptable methods of processing laundry.

Other Healthcare Settings

In some healthcare settings (i.e., ambulatory care, behavioral health units, rehabilitation), linens and clothing may not be routinely determined as being contaminated with blood or body fluids. These items are often washed in designated locations near patient care areas or by the patients themselves as part of their activities of daily living. In these situations, guidelines should be developed to ensure that both staff and patients are instructed on appropriate processing procedures. These should include the following instructions:

- Wear disposable nonsterile gloves for handling soiled linen.
- Rinse all fecal matter from clothing before washing.
- Handle soiled linen as little as possible and with minimum agitation.
- Transport all items to washers in hamper or plastic bags.
- Avoid overloading the washing machine.
- Normal laundry cycles should be used in accordance with the washer and detergent manufacturer's recommendations.
- Disinfection of the washer tub and dryer is unnecessary.
- Perform hand hygiene after handling soiled items.

Antimicrobial Textiles

The availability of medical fabrics treated with antimicrobial agents has increased considerably over the last few years. A wide variety of metals and chemicals are currently used to confer antimicrobial properties on fabric including gold, silver, copper, titanium, triclosan, chitosan, chitooligosaccharides, quaternary ammonium compounds, and zeolite-containing compounds. The antimicrobial effect is achieved by either chemically treating the fabric or finished product, or by incorporating the substances directly into the fibers during the weaving process. [14] These antimicrobial technologies have demonstrated varying degrees of effectiveness under laboratory test conditions in inhibiting growth and/or killing bacteria on the surface of fabrics. The inhibition of bacterial populations on fabrics during contact periods range from days to weeks. [15,16,17] Antimicrobial activity may be affected by a number of factors including properties of the challenge microorganism(s), intrinsic moisture content of the fabric, length of contact time, method of treatment application, type of fabric, and number of wash cycles after treatment. [14] The durability of these products is variable; the antimicrobial effect in some textiles has been depleted or severely diminished after 10 or fewer wash cycles. [15]

Antimicrobial results are achieved through two mechanisms of action. The first consists of chemicals that operate on a controlled-release mechanism; the antimicrobial is slowly released from a reservoir on the surface of the fabric or from the interior of the fibers. However, once the reservoir is depleted, the fabric will no longer possess antimicrobial properties. In addition, the antimicrobials that are released to the environment may interfere with other desirable microbes. The second mechanism of action consists of antimicrobial agents that are bonded to the fabric. The antimicrobial action has a biocidal effect only on the microbes that are present on the fiber surface, and does not affect microbes in the surrounding environment. These substances may potentially wear off or become deactivated. [18]

Concerns have been raised over the safety of antimicrobial products on human health and the environment. Potential adverse effects include sensitization, disturbance of the ecology of the skin, toxic side effects, cytotoxicity, carcinogenicity, and ecotoxicity. Triclosan and quaternary ammonium compounds, for example, have been associated with dermal adsorption. [19] A 2010 study by Kulthong et al. reported that silver nanoparticles from silver coated fabrics were released after incubation in artificial sweat. [20] The first clinical study linking a reduction in HAIs with the use of antimicrobial textiles was published in 2014 by Lazary et al. [21]

HAI rates in two analogous patient cohorts on a head injury care ward were evaluated over two six-month parallel periods before (period A) and after (period B) replacing all the regular non-biocidal linens

and personnel uniforms with copper oxide impregnated biocidal products. During period B, in comparison to period A, there was a 24% reduction ($p < 0.05$) in HAIs. The authors conclude that the use of biocidal copper oxide impregnated textiles in a long-term care ward may significantly reduce HAIs. More clinical studies are needed to understand the association between antimicrobial fabrics and HAI incidence.

The Environmental Protection Agency's (EPA) Office of Pesticide Programs (OPP) has the responsibility under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) to regulate the registration of antimicrobial products used to control pathogenic bacteria, viruses, and other microorganisms for a variety of uses. The FIFRA requires the registration of any substance intended to prevent, destroy, repel, or mitigate pests (including microorganisms). EPA regulations in 40 CFR 152.25(a) exempt certain treated articles and substances from regulation under FIFRA if specific conditions are met. [22]

In the United States, textiles usually fall into the Treated Articles Exemption. Consumers may distinguish such products by the absence of the EPA's pesticide registration number of the registered pesticide used for protecting the article itself. An EPA registration number would be found on the product label. The intended use and manufacturer's claim for an antimicrobial textile product directs its regulation.

Articles or products that claim to be effective in controlling microorganisms such as *E. coli*, *S. aureus*, *Salmonella sp*. or *Streptococcus sp*. must be registered as a pesticide. EPA requires the submission of chemical data in support of the public health labeling claims and patterns of use of the product. [23]

Home Laundering of Healthcare Attire

The issue of home laundering of scrubs or other surgical attire is controversial and much attention has been recently focused on the microbial load present on these textiles. The Guidelines for Environmental Infection Control in Health-Care Facilities (2003) admit that experts are divided regarding the practice of transporting clothes worn at the workplace to the healthcare worker's (HCW's) home for laundering. [1]

OSHA regulations prohibit home laundering of items that are considered personal protective apparel or equipment (e.g., laboratory coats); however, this regulation does not extend to uniforms and scrub suits that are not contaminated with blood or OPIM. [2]

Numerous studies have demonstrated the contamination of HCW's attire including white coats, ties, and uniforms with potentially pathogenic microorganisms. [24,25,26,27,28,29] The first report of a positive correlation between bacterial contamination of HCWs' hands and uniforms was published by the American Journal of Infection Control (AJIC) in 2012. Munoz-Price et al. (2012) cultured the hands and uniforms of physicians, nurses, and other healthcare professionals (e.g., therapists, technicians) from five intensive care units. Eight-six percent of the 119 HCWs in the study demonstrated bacterial growth on their hands. Eleven percent grew *S. aureus*, 6% grew *Acinetobacter* spp., and 2% grew *enterococci*. The presence of pathogens on the hands was associated with a greater likelihood of the presence of pathogens on white coats. This association was not observed between hands and scrubs, however. The authors postulate that this may be explained by the different laundering frequency of these garments. [27]

Several studies have raised questions about the safety and efficacy of home laundering of surgical attire. Twomey et al. (2010) reported that the aerobic bacterial bioburden associated with surgical scrub attire had significantly greater contamination among home-laundered attire than scrubs laundered by the healthcare facility, scrubs sent out by the facility to a third-party company for laundering, or single-

use/disposable scrubs. They concluded that home-laundering is not as effective as facility or third-party laundering in decontaminating surgical scrub attire. [30] Similar results were reported by Nordstrom et al., who conducted a comparison of bacteria on new, disposable, laundered, and unlaundered hospital scrubs and discovered significantly higher bacteria counts were isolated from home-laundered scrubs and unwashed scrubs than from new, hospital-laundered, and disposable scrubs. [31]

Three cases of postoperative *Gordonia bronchialis* sternal infections after coronary artery bypass grafting surgery were reported in a 2012 study by Wright and colleagues. *Gordonia bronchialis* was isolated from the scrub attire, axilla, hands, and purse of a nurse anesthestist, and was implicated as the cause of the SSIs. Cultures taken from her roommate, who was also a nurse, showed the same microorganism. The authors concluded that the home washing machine was the likely bacterial reservoir. This study is the first to demonstrate a causal relationship between home laundering and human disease. [32]

HLAC addresses this issue in their standards and explains, “it should be noted that the use of home washers of the processing of reusable surgical textiles is not recommended. Home washers are designed for retail situations, and this design does not take into account industrial environments and hazards addressed in the OSHA Bloodborne Pathogen standard.” [11]

Although the CDC describes the matter as unresolved, AORN opposes the practice of permitting surgical personnel to launder soiled scrubs at home. The revised “Guideline for surgical attire” published in AORN’s *Guidelines for Perioperative Practice* (2015) recommends that scrub attire and cover apparel should be laundered in a health care-accredited laundry facility after each daily use and when contaminated. [33] Home laundering practices are not subject to quality monitoring, and “home washing machines may not have the adjustable parameters or controls required to achieve the necessary thermal measures (e.g., water temperature); mechanical measures (e.g., agitation); or chemical measures (e.g., capacity for additives to neutralize the alkalinity of the water, soap, or detergent) to reduce microbial levels in soiled surgical attire.” [33]

Healthcare administrators and infection prevention teams must weigh the potential risk of infection transmission against the cost savings achieved through having staff launder their own scrubs. HCWs should be educated on the potential for uniforms to become contaminated and steps they can take to minimize transmission of microorganisms within the healthcare setting as well as to their home environment.

Microbiological Sampling of Textiles

Microbiological testing of laundered textiles is conducted routinely in Europe and Australia as a requirement of their healthcare regulation programs. [34,35] The Certification Association for Professional Textiles Services Administration (CAPSTA), which has 400 members in 15 European countries, Japan, China, and the United Arab Emirates, has established safe microbial levels for laundered textiles as 20 colony-forming units (CFU) per square decimeter (PSD). This microbial threshold has now been adopted by the European Union. Microbial testing of textiles has recently been established in the United States with the establishment of TRSA’s “Hygienically Clean Certification” program, which requires third-party, quantified biological testing and inspection. [36] Testing is performed using Replicate Organism Detection and Counting (RODAC) plate counts quarterly and United States Pharmacopeia (USP) 62 (Microbial Enumeration of Nonsterile Products) criterion semiannually, which necessitates the complete absence of

specified microorganisms, including *S. aureus*, *P.aeruginosa*, and *E. coli*. The certification program consists of four phases (1) initial qualification in which 2 textile products are tested, (2) probationary period which tests 6 different textiles, (3) quarterly quality control testing (testing 28 textiles in a 3 year period) and (4) triennial onsite inspections where at least once every three years, two items will be selected for microbial testing. The AORN Seal of Recognition has been awarded to Hygienically Clean Healthcare, which communicates to the perioperative and health care community that Hygienically Clean Healthcare certification is dedicated to excellence in patient care.

The Guidelines for Environmental Infection Control In Health-Care Facilities (2003) does not currently recommend routine microbiologic sampling of clean textiles. [1] Microbiologic sampling during outbreak investigations is appropriate however, if epidemiologic evidence indicates a role for healthcare textiles and clothing in disease transmission.

Conclusions

Healthcare textiles have become an important issue in infection prevention and control and laundry services are an integral part of the multidisciplinary team approach necessary for improved patient outcomes. The use of a defined laundering process, the parameters of which are established in the industry is essential for the production of hygienically clean textiles. The goal for healthcare laundry is achieved by consistent monitoring of the entire laundering process, coupled with best practices in infection prevention for laundry personnel and a well designed, properly functioning laundry in accordance with accepted industry standards.

Future Trends

Healthcare textiles is one of most rapidly growing sectors in the technical textile market. Advancements in medical technology, population growth rates, changes in the demographics associated with an aging population and renewed commitment to the elimination of HAIs as well as the demand for greater transparency are all driving the healthcare textiles market.

There have been many novel developments in the composition of hospital linen products that promise to decrease the chance of carrying disease, increase a patient's ability to heal, and lessen the likelihood of the patient developing skin issues like bed sores. Smart or “intelligent” textiles refer to textile materials or engineered structures that can potentially sense, react, and/or adapt to environmental conditions. Nano-sized particles can be used to change the surface area of fabrics used in healthcare, which increases surface tension and creates a barrier to contaminants and fluids, such as blood. The textile industry has developed different methods for obtaining fabrics and fibers with an antimicrobial action for use in hospital environments and for other purposes.

Antimicrobial chemicals such as copper oxide, silver, gold, triclosan, and titanium dioxide, among others, have been impregnated into such items as linens, respiratory masks, isolation gowns, laboratory coats and uniforms. Antimicrobial cubicle curtains and shower and window treatments are commercially available for use in patient rooms. Quality issues such as potential toxicologic and allergic side effects, potential selection for resistant microorganisms with long-term use, environmental issues, and persistence of the antimicrobial effect require further investigation. Well-designed studies are needed to evaluate the association between HCT and patient colonization and infection. Additional clinical studies of the risks and benefits of antimicrobial textiles are essential to inform their use in healthcare.

Commercial laundries typically consume enormous amounts of both water and energy, which pose substantial environmental concerns. The environmental impact of commercial laundry operations is under intense scrutiny; there is constant pressure to be more efficient with natural resources such as water, and to reduce the amount of chemical waste, which is put into the environment by laundry processes.

Healthcare textiles are a dynamically expanding industry. From the accreditation process network to the creation of environmentally friendly and clean healthcare fabrics to the utilization of smart technology, the potential range of uses for medical textiles will continue to increase and offer the potential to reduce HAIs.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Maintenance and Engineering

Author(s): Stephen D. Cutter, MBA, HFDP,CHFM, SASHE
Director of Facilities

Dartmouth-Hitchcock Medical Center
Lebanon, NH

Published: October 3, 2014

Abstract

Healthcare settings vary in a number of ways, including type and physical structure of the facility, patient services, community surroundings, and geographical location. Major areas of responsibility of the maintenance and engineering staff relate to buildings, utilities, associated equipment, and property or grounds. Within these components are multiple activities ranging from preventive maintenance through major projects. A strong working relationship between the infection preventionist and maintenance and engineering staff is essential to maintain a safe environment and minimize potential risks. This chapter outlines risk elements that are common in many facilities and provides examples of interventions to address these challenges.

Key Concepts

- Settings for healthcare vary widely, both in size and scope of services.
- Maintenance and engineering responsibilities encompass many areas, including facilities/buildings, utilities, equipment, and grounds.
- Maintenance and engineering staff and infection preventionists work in partnership to provide a safe environment of care.
- Maintenance and engineering activities, facility components, and equipment have identifiable risks and interventions; therefore, recognition of the major routes of microbial spread—air, water, and surface—is fundamental to identifying risks and formulate preventative strategies.
- Preparedness through prudent and proactive maintenance is better than a reactive approach for preventing infections.
- Emergency preparedness is integrated into maintenance and engineering operations.

- Sustainable mechanical systems for energy management that include risk assessment provisions support hazard control in healthcare facilities.
- Education and training of maintenance and engineering staff and contracted workers is essential for patient, visitor, and worker safety, as well as protection of the facility and community served.
- Performance improvement activities may be used to improve maintenance and engineering processes and systems.

Background

Healthcare facilities that provide direct patient care differ broadly in size and complexity, ranging from storefront practices to multibuilding campuses. The maintenance and engineering (MAE) staff composition also varies and may range from a part-time or as-needed "handyman" to a complex department with numerous employees and resources. Facility and utility components, as well as maintenance of buildings, support systems, equipment, and grounds, are often included in MAE responsibilities. Consideration includes compliance with applicable codes, regulations, standards, and guidelines.[1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22](See also **4. Accrediting and Regulatory Agencies**.)

Regardless of the size and scope of services, there are standard elements that must be considered to provide a safe setting for workers, patients, visitors, and others. Part of the goals and recommendations for an effective infection prevention and control program include minimizing risks of infection regardless of healthcare setting.[7,8,9,11,12,17,23,24,25,26]Therefore, the infection preventionist (IP) should develop a working knowledge of the challenges within the MAE arena and partner with MAE personnel to help identify risks and provide guidance for appropriate interventions. The organization's culture of safety can greatly affect worker health and patient outcomes.[12,17,18,27,28,29,30,31,32]

Basic Principles

Venues that offer healthcare services vary widely and include urban, suburban, and critical access hospitals; long-term acute care facilities; chronic and long-term care settings; skilled nursing facilities; ambulatory surgery sites; dialysis centers; rehabilitation centers; hospice; urgent care centers; clinics with one or more specialties; single-clinician practices in rented buildings; endoscopy centers; dentistry and oral surgery; behavioral and substance abuse centers; school clinics; infirmaries at correctional facilities; health department clinics; employee/occupational health centers; in vitro fertilization clinics; some research facilities; and other unique sites (see also chapters on specific practice settings and services; refer to index and/or table of contents).

Responsibilities of the MAE department vary in accordance with the type and size of healthcare facility but typically include the following:

1. Equipment repair and maintenance
    a. Varies broadly but would typically include patient beds, table, furniture, wheelchairs, scales, sterilizers, laboratory equipment
2. System maintenance and repair
    a. May include pneumatic tube systems, nurse call and code blue systems, duress systems, access control systems, elevators and lifts, fire alarm systems

3. Heating, ventilation, and air conditioning (HVAC) systems
    a. Critical to a safe environment, these systems include air supply, return and exhaust systems, heating, cooling, and humidification and filtration systems.
4. Utility systems management.[1,3,4,5,7,9,13,16,33,26,29,32,34,35] In addition to HVAC equipment noted above, utility systems may include:
    a. Electrical system and emergency power systems
    b. Medical gas systems including oxygen, medical air, nitrogen and medical vacuum, as well as piped anesthesia gases
    c. Potable water and wastewater systems
    d. Boiler, steam, and hot water systems
    e. Pager and communication systems
5. Facility infrastructure maintenance and repair
    a. Includes elements such as roofing, window systems, flooring, ceiling and walls, doors and hardware, etc.
6. Grounds and landscaping
7. Building renovations and alterations
    a. Responsibility for this work varies greatly but typically includes planning, design, and construction activities. Understanding the processes that frame this work is critical for the IPs so that they can provide input at the appropriate time in the process.
8. Emergency preparedness[15,16,25,35,36]
    a. An organization's emergency preparedness program is typically a collaborative effort but the MAE management and staff will have a strong role, as the systems noted above are important systems in the program.

See also **108. Laboratory Services**; **113 Waste Management**; **114 HVAC**; **115 Water Systems Issues**; **116 Construction and Renovation**; and **119 Emergency Management**. Sustainable management of essential ventilation air and water quality requires commitment to the attention necessary to ensure consistent control of comfort and hazards associated with healthcare facilities. These hazards are identified within the environment of care, especially those associated with infection prevention systems.

Collaboration between MAE personnel, IPs, and other safety professionals will help establish appropriate measures that maximize risk reduction; such strategies should be integrated into MAE activities. Effective education and training of department and contracted employees must include infection prevention and safety components.[3,4,12,17,17,31,32,37,38] (See also **3. Education and Training**; **27 Hand Hygiene**; **29 Isolation Precautions**; **100 Occupational Health**; **101 Occupational Exposure to Bloodborne Pathogens**; **103 Immunization in Healthcare Personnel**; and **104 Pregnant Healthcare Personnel**.)

Effective communication, measurement, documentation, analysis, and interventions are crucial steps for a successful program. Performance improvement activities may be incorporated to appraise actions or process improvement changes and to evaluate success.[7,12,13,17,23,29,30,39,40,41,42] (See also **16. Quality Concepts**, and **17 Performance Indicators**.)

Standards For The Maintenance And Engineering Department

General Information Related to Infection Risks

Depending on the facility, the MAE department maintains, repairs, and installs various systems, such as those related to electrical power; ventilation; potable and high-purity water; waste management, including biologic and other hazardous substances; septic/sewage; thermal and humidity control; decontamination and sterilizing equipment; transportation; and systems used for research activities. The MAE may also provide support for infection prevention and control functions including sinks to facilitate hand washing; sanitary storage and transportation of supplies; HVAC systems to control airborne spread of infectious agents; effective filtration to meet a variety of air quality requirements including high-efficiency particulate air (HEPA) filtration for protective environments (PE); special filtration in operating and procedure rooms; and special exhaust systems to control fumes and infectious agents (sputum induction booths, biologic safety cabinets, plume capture, pathology dissection, and autopsy). Such activities often involve the potential for transmission of infectious agents or other hazards to the individuals (workers, patients, visitors, students, and others) in the immediate or adjacent area and to the internal and external environment.[1,2,5,6,7,8,11,12,13,14,16,19,21,23,24,25,28,29,34,35,43,44,45,46,47,48,49,50,37,38,51,52,53,54,55,56,57,58,59,60,61,62,63,64,65,66]

Identifying potential sources of microbes and their routes of spread—airborne, waterborne, and surface/contact—should be included in education and training for MAE employees and contracted individuals.[3,5,6,7,12,17,18,19,27,28,29,31,32,50,55,59,64,66]Additional educational topics should include procedures to reduce spread, use of supplies and equipment necessary to minimize contact with infectious material, and safe repair of equipment or other components. Special precautions are required when workers enter rooms where patients may be infectious (e.g., airborne infection isolation [AII] rooms or bronchoscopy suites) and include both routine maintenance and urgent/emergent activities.[6,7,56]Instruction should integrate the facility's communication procedure(s) to ensure that others are not put into harmful situations and that a potential hazard is recognized, reported, and addressed in a timely manner. (See also **3. Education and Training**; **27 Hand Hygiene**; **29 Isolation Precautions**; **100 Occupational Health**; **101 Occupational Exposure to Bloodborne Pathogens**; **103 Immunization of Healthcare Personnel**; and **104 Pregnant Healthcare Personnel**.)

As noted above, providing appropriate education and training to MAE staff in infection risks, transmission methods, and risk mitigation strategies is a key strategy in infection prevention. Likewise, MAE staff and leadership have a responsibility to provide education and training to the facility's IPs in how facility systems operate to minimize the risks of infection transmission. Specifically, there is a great opportunity for infection prevention professionals and MAE staff to collaborate and to learn and understand how utility systems such as HVAC, water, and wastewater systems are designed and operated.

Specific Activities of the Maintenance and Engineering Department: Risks and Interventions

Maintain and repair equipment used for patient care[6,7,8,19,20,23,25,29,49,61,67,68,69]

Risks

- Equipment can become contaminated with blood, secretions, excretions, and/or drainage with potential for colonization or infection.
- Tools and components used in repair activities can become contaminated and become fomites for transmission of infectious material.

- Contamination of equipment or other surfaces during maintenance or repair activities may have potential for subsequent spread of microbes to patients or others.
- MAE staff's work activities in sensitive patient care areas may result in release of potentially infectious microbes. Examples may include accessing equipment panels in the operating room (OR) suite, working on a patient monitor in the intensive care unit, or repairing a ventilator in a room with an immunocompromised patient.
- Malfunctioning equipment may cause the release of hazardous agents.

Interventions

- When contamination (e.g., spills of medication or body fluids) of a medical device or equipment occurs, it should be removed from the patient care environment and appropriately cleaned and disinfected according to manufacturer's instructions or per facility policy/procedure. The equipment should not be returned to service until it is determined to be disinfected so that it will not become a potential hazard to patients or personnel.
- Evaluate equipment prior to purchase for ease of cleaning and disinfection or sterilization, ease of disassembly/reassembly, access to components, durability, and other features.
- Develop a policy/procedure to communicate (color-coded bag and/or biohazard label) that equipment is potentially contaminated.
- Clean and decontaminate equipment with approved germicidal detergent before and/or after maintenance, as indicated.
- Wear appropriate personal protective equipment (PPE) when in potentially hazardous areas (e.g., N95 respirator for entering an AII room).
- Wear appropriate size and type of protective gloves (cut resistant) when handling equipment that could inflict cuts or punctures or when contamination is suspected (disposable exam gloves).
- Wear appropriate attire in controlled areas in accordance with the facilities infection control protocols (e.g., jumpsuit, head and foot covers in the OR).
- Limit tools/equipment taken into controlled areas and ensure that items that are needed are clean and free of contamination. Electronics (televisions, computers, monitors, and lighting systems) accumulate dust due to electrostatic charges. Methods to safely remove dust (e.g., HEPA vacuum or specially treated cloth) are preferred over using pressurized air to blow out dust, especially in areas that could be affected by contamination (e.g., locations with immunocompromised patients, invasive procedures areas, storage of clean/sterile supplies areas, laboratories, pharmacy, or kitchens). Where cleaning methods that create dust and debris are used, the work should be completed with the patients removed and appropriate cleaning conducted before the patients are returned.
- Large-equipment removal (x-ray, laboratory instruments, whirlpools, etc.) may require special cleaning or protective wrapping to control accumulation of dust when transporting through the facility. Conversely, equipment that cannot be removed for maintenance projects should be protected.
- Perform routine cleaning with approved methods to reduce accumulation of dust and debris.
- Planned maintenance programs should be developed and implemented to minimize the risks of critical equipment failure.
- Provide and document training in decontamination procedures, PPE, and hand washing to minimize patient and worker exposure during maintenance and repair activities.
- Promptly perform first aid (rinse, wash, flush) and report injuries or exposures that occur while working with potentially contaminated equipment.

(See also **21. Risk Factors Facilitating Transmission of Infectious Agents**; **27 Hand Hygiene**; **29 Isolation Precautions**; **55 Endoscopy**; **67 Respiratory Care Services**; **68 Surgical Services**; **100 Occupational Health**; **101 Occupational Exposure to Bloodborne Pathogens**; **106 Sterile Processing Services**; **107 Environmental Services**; and **119 Emergency Management**.)

Maintain and repair existing structures and equipment, make recommendations for appropriate materials in construction and renovation planning[1,3,5,6,7,8,9,12,17,23,25,34,50]

Risks

- Deterioration and damage to surfaces and finishes may result in loss of intact, cleanable surfaces, leading to potential environmental reservoirs for a variety of microbes.
- Removal of damaged building components such as stained ceiling tiles and water-damaged surfaces without taking appropriate precautions can allow for the airborne transmission of potentially infectious organisms such as fungal spores.
- Water leaks on almost any material with an organic structure such as wallboard, acoustical ceiling tiles, or insulation, may initiate growth of ubiquitous fungal spores. In addition to organic materials, soil and dirt buildup on any surface can be a food source for organisms. These can then become reservoirs for a variety of opportunistic fungal spores such as *Aspergillus fumigatus*.
- Unprotected openings in any building can provide for infiltration of unconditioned air. This may affect critical areas that require special ventilation or pressurization.
- Inappropriate materials selected during the building design, construction, or renovation can result in elevated risks of infection transmission. Flooring, wall, and ceiling materials should be selected for appropriate levels of cleaning.[1]

Interventions

- Evaluate surfaces, materials, and furnishings used for new construction and renovation projects; consider those that are nonporous and will resist deterioration and damage while maintaining durability for routine cleaning/disinfection and management of blood/body fluid spills.
- When mold (surface growth) is noted, appropriate efforts should be instituted to assure contamination control. An infection control risk assessment (ICRA)[1]should always be conducted and appropriate infection control risk mitigation recommendations (ICRMR) developed and implemented (refer to). Worker protection is also a consideration. (For example, *Guidelines on Assessment and Remediation of Fungi in Indoor Environments,*by the New York City Department of Health and Mental Hygiene, is available to help determine measures to be taken for bio-aerosol management [refer to Supplemental Resources].)
- Assess the risks of routine maintenance of above-ceiling equipment and structures with infection prevention staff and develop standard operating procedures (SOPs) to minimize risks.
- Replace or repair damaged structural surfaces (e.g., countertops, sinks, floors, or tiles) as needed; use previously developed SOPs during repairs.
- Ensure maintenance of exterior surfaces to prevent air and water infiltration.
- Develop policies and procedures to be followed in the event of water intrusion, leaks, spills, or drain/sewer backups. This should be the work of a multidisciplinary committee that includes representation from risk management, safety, infection prevention, environmental services as well as

MAE. Consider the *Guidelines on Assessment and Remediation of Fungi in Indoor Environments*[70] as a guidance document. Concepts include:

- Use a moisture meter for objective evaluation of wet materials. Maintain water content of material below established levels for preventing microbial growth on the material (i.e., less than 20 percent water content). An infrared camera may be used to discern "hidden" (e.g., behind walls) wet areas or leaks.
- Replace/repair wet ceiling tiles or other surfaces that have been wetted with clean water and that cannot be dried within 72 hours.
- Replace all materials that have been wetted with unclean (gray or brown) water.
- If water-damaged surfaces/areas are recognized as supporting mold/mildew, initiate necessary containment precautions before and during remediation; apply appropriate methods to clean and decontaminate prior to use or occupancy (i.e., apply an ICRA).

(See also **23. The Immunocompromised Host**; **77 Environmental Gram-negative Bacilli**;**78 Fungi**; **95 Tuberculosis and Other Mycobacteria**; **114 HVAC**; **115 Water Systems Issues**; and **116 Construction and Renovation**.)

Maintain or repair HVAC systems; failure to do so may result in potential airborne colonization or infection for patients, visitors, and workers[1,3,4,5,6,7,8,18,25,26,34,33,44,45,46,71,47,48,72,49,73,74,50,75,36,42,52,53,55,58,59,62,76,77,78,79]

Risks

- Temperature and/or humidity levels that are out of the acceptable range for the room/area can result in sweating or condensation on surfaces.[1] This condensation may result in microbial growth.
- Inappropriate pressure relationships may allow for the dissemination of contaminated air, disruption of controlled airflow, or inappropriate airflow during isolation precautions or invasive procedures.[1]
- During filter changes, dissemination of dust particles may occur in the ductwork or areas surrounding the filter change; this dust may harbor opportunistic environmental microbes.
- Faulty humidification systems can cause spraying of condensate or steam on filters, leading to compromised filtration efficacy. Faulty pressure relief can cause leaking from steam debris that can create ideal conditions for mold growth.
- Inappropriately maintained cooling towers can increase the risks of waterborne pathogens such as *Legionella pneumophila* or *Pseudomonas aeruginosa*.[80]

Interventions

- Evaluate HVAC and local area exhaust systems for actual ventilation conditions when planning for new construction and renovation projects to ensure that there is adequate capacity for planned changes.
- Ensure commissioning is completed for new construction, renovation, or major changes to the HVAC system.[81]
- Schedule routine maintenance of ventilation systems to ensure that heating, cooling, humidification, and filtration subsystems are working as designed.

- Provide systems for the monitoring of critical elements related to HVAC control, including outside air/return air parameters (temperature, relative humidity, pressure relationships) in critical areas, air changes per hour for comfort and infection control, capture of hazardous gases, and fumes or other contaminants from local exhaust ventilation (e.g., laser or electrocautery plume capture, biological safety cabinets, chemical/fume hoods, stove canopies, welding activities). Validate existing conditions of special ventilation rooms where airflow direction is important as part of infection prevention (e.g., PE and AII rooms, surgical and procedure rooms, laboratories, pharmacies). This should be accomplished with calibrated equipment independent of building ventilation system controls and monitoring equipment.
- Ensure that procedures are established and followed for corrective actions when monitoring indicates unacceptable conditions per recommendations from manufacturer and/or published guidelines or standards. For example, a room monitoring device does not zero on digital readout during calibration if an alarm (sound or light) malfunctions or the enunciator for the monitored room fails.
- Schedule preventive maintenance to include regular cleaning of air intakes, supply/exhaust/return vents, ducts, and cooling towers.
- Recognize steam spraying on filters or other malfunctions that can cause mold growth; correct the condition and follow the established remediation protocols.
- Ensure that employees have appropriate PPE (e.g., dust mask or respirator) during filter changes and other maintenance activities on HVAC systems and cooling towers where the task results in anticipated risks of exposure.
- Develop and follow procedures for the inspection and replacement of air filters that minimizes the risks of transmission. Ensure that HVAC systems are shut down when these activities occur.
- Notify specific patient care areas in advance of filter changes or other scheduled maintenance that will interrupt ventilation so precautions can be taken for patients and employees affected[7](e.g., mask patient in AII room).
- Signage and labeling of ducts and controls that service special ventilation areas (e.g., AII room, bronchoscopy suite, biological safety cabinet, areas where ethylene oxide is present) should warn of possible hazards and specific areas affected by the maintenance activity (e.g., operating room, nuclear medicine, laboratory, central processing, research); signs should provide contact information (e.g., telephone number) requesting notification or permission prior to servicing.
- Develop and follow contingency plans for ventilation outages. Contingency plans should be developed with input from clinical and infection prevention staff and should be based on risk aversion for respective outages. For example, PE rooms may have redundant or backup portable filters, especially if major fans are not on emergency power backup. Safety procedures within the unit may also include practices such as keeping doors closed whenever possible until ventilation is reestablished.
- Education and training content for IP, MAE, and clinical staff should include information on the importance of scheduling and on communication protocols to ensure minimal impact of ventilation system maintenance procedures on the safety of patients or employees. It should stress the importance of ventilation control in the OR and other specialty areas and contrast the differences between positive and negative pressure relationships.
- Include education and training for contractors who will be working with these systems; monitor to ensure compliance with expectations.
- Provide emergency ventilation service to special ventilation areas affected during planned and unplanned interruption to ensure that ventilation control for specialty areas (e.g., OR, PE, and AII

rooms) is not compromised. These measures may include the appropriate type and location of portable HEPA units, how to block off or filter air supply, and/or return outlets.

- Develop policies and procedures for safe restoration of the system after planned or unplanned interruption, include communication with tenants and verification testing, as deemed necessary, based on the area.

(See also **23. The Immunocompromised Host29 Isolation Precautions**; **84 *Legionella pneumophila***; **115 Water Systems Issues**; **119 Emergency Management**; and **120 Infectious Diseases Disasters**.)

Maintain and repair protective hoods, biologic safety cabinets, and other local exhaust and ventilation/containment systems[1,7,15,21,43,46,49,37,59,62,66,77,78]

Risks

- Improperly maintained or nonfunctioning hood exhaust systems may result in airborne contamination of surrounding areas, staff, or area elements such as pharmaceuticals clean supplies or equipment.
- Improper function of local exhaust ventilation systems (e.g., biologic safety cabinet, portable sputum induction booth, antineoplastic preparation hood, plume capture) may result in improper airflow within the system and result in staff or patient exposure of potentially pathogenic organisms or other hazards.

Interventions

- Select appropriate systems based on design parameters, effectiveness, anticipated hazards, location, and compatibility with other equipment or systems (e.g., does not interfere with general dilution ventilation, does not block access to other equipment or controls, will not impair egress, will not exhaust near intake).
- Schedule and document routine monitoring of local exhaust ventilation systems, including measuring the capture velocity and the appropriate direct exhaust or filter mechanism (e.g., HEPA); include verification and replacement.
- Schedule, perform, and document regular preventive maintenance, including air intake, filters and blowers inspection, lubrication, and repair or replacement of parts.
- Implement corrective actions when monitoring indicates unacceptable conditions.
- Coordinate maintenance and repair activities with workers and affected areas.
- Provide certification for equipment (e.g., biologic safety cabinets and chemical flow hoods) at appropriate intervals to validate performance.
- Provide installation and maintenance of filtration systems as appropriate.
- Provide employee training for both operating and maintenance personnel to ensure that safety measures are followed.
- Follow organizational employee/occupational health protocol if exposure to hazards may have occurred.
- Label ductwork to alert workers of potential hazards, supply appropriate PPE, and include communication with the user when scheduling maintenance or shutdown.
- Provide training for personnel required to work on microbial sensitive material in the biosafety equipment to help prevent false-positive results or contamination.

(See also **67. Respiratory Care Services**; **101 Occupational Exposure to Bloodborne Pathogens**; **108 Laboratory Services**; **110 Pharmacy Services**; **113 Waste Management**; **114 Heating, Ventilation and Air Conditioning**; **65 Postmortem Care**; **119 Emergency Management**; **120 Infectious Diseases Disasters**; and **121 Animal Research and Diagnostics**.)

Maintain and repair plumbing supply and drainage systems[1,2,3,5,7,8,9,16,23,35,82,41,51,57,58,60,61,64,67,68,81,83,84,85,86,87,88,89,90,91,92,93,94]

Risks

- Nonfunctional or improperly functioning hand-washing facilities result in inadequate hand washing by patient care and support personnel.
- Leaking fluids in any area, especially critical areas (e.g., operating and delivery rooms, nursery, food preparation, serving and storage areas, or central supply) may cause fungal or microbial growth and provide an elevated risk of contamination of staff, patients, food, or patient care items.
- Leaks and spills create conditions ideal for growth of opportunistic fungi or other organisms (e.g., *Aspergillus, Pseudomonas, Acinetobacter*).
- Improperly maintained water supply components such as aerators, ice machines, or common plumbing may provide a reservoir for proliferation of microorganisms (e.g., atypical *Mycobacterium*).
- Stagnation of potable water (e.g., dead-end connections, poor design of system flow) can result in the creation of reservoirs that can exacerbate chlorine breakdown and increase the risk of microbial growth.
- Development of biofilm and sediment in pipes (e.g., aerators) may result in high levels of microbes (e.g., *Legionella, Acinetobacter, Pseudomonas*).
- Stagnant water in uncapped drains (floor drains or infrequently used fixtures) can cause obnoxious odors or become a reproductive reservoir for insects such as sewer flies.
- Interruptions of the plumbing system can cause sediment and stagnant areas in the potable water distribution system to be disturbed and cause the release of microbes (e.g., *Legionella*or atypical *Mycobacterium*) into the water supply.
- During repairs of drainage pipes (e.g., unclogging toilets and pipes), employees may be exposed to biologic, chemical (e.g., chemotherapy), and medication waste.
- Backflow, flooding, or backsplash may cause environmental contamination of surfaces, supplies, or equipment.
- An outage of the facility's water supply system may require an alternative water supply for basic sanitation, hand washing, bathing, drinking, cooking, or other needs.
- Disruption of the water supply compromises the availability of safe, plumbed emergency eye wash and shower stations.
- ;Failure to maintain and routinely flush emergency eye wash and shower stations increases likelihood of microbial growth.

Interventions

- Appraise potable water and sewer systems for design or redesign/improvement opportunities as appropriate when planning new construction and renovation projects and when adding new equipment connected to the system (e.g., reprocessing of endoscopes, hemodialysis).

- Conduct an assessment of the facility's water systems to see what parts of those systems are at elevated risk for contamination. Develop risk mitigation strategies for areas identified as high risk (cooling towers, water heaters, water filter systems, etc.).
- Schedule regular preventive maintenance of laboratory and sink fixtures, vacuum breakers, water supply system, ice machines, floor drains and pipes, flushing devices, special water treatment devices, hot water heaters, and storage tanks.
- Conduct a risk assessment regarding the use and maintenance of faucet aerators in the patient care environment. Consider periodic maintenance/replacement of aerators in sensitive areas.[5]
- Provide appropriate PPE for workers servicing sewer lines or toilet facilities.
- Maintain tools and equipment in a clean condition, especially those used in patient care and support environments.
- Maintain and repair steam supply system as indicated.
- Recognize and promptly correct water leaks; follow established SOPs for remediation of areas/materials that have been wetted.
- Use moisture-monitoring equipment to detect and provide objective measurement(s) of drying. Infrared cameras will allow for expedient visual analysis and determination of water damage for immediate wet material removal.
- Provide sanitation training for cleanup of sewerage backup.
- If mold is encountered after water flooding or is simply discovered, follow established organizational procedures (see "Maintain and repair existing structures and equipment, make recommendations for appropriate materials in construction and renovation planning" section above).
- Ensure that MAE employees, contracted workers, and service representatives receive education and training that is appropriate to their job; specify in the contract or service agreement.
- Maintain ongoing communication between maintenance management, operational supervisors, and the IP in order to discuss potential problems associated with plumbing and unusual infections (e.g., *Legionella*cluster).
- Develop policy and procedure for provision of services and supplies during planned and unplanned interruption of potable water and sewer service; include protocol for safe return of water/sewer once service is restored (e.g., systematic flushing from larger to smaller, need for chemical and/or heat treatment, stuck valves, cleaning of debris or sediment).

(See also **23. Maintain and repair steam supply system[1,5,7,84]

Risks

- Inadequate functioning of steam sterilizers resulting in insufficient sterilization of medical instruments and devices.
- Incomplete sanitation of cookware, dinnerware, utensils.

- Faulty humidification systems can cause spraying of condensate or steam on filters, leading to compromised filtration efficacy. Faulty pressure relief can cause leaking from steam debris that can create ideal conditions for mold growth.

Interventions

- Evaluate design and requirements when planning renovation and construction projects.
- Develop communication protocols with affected departments (central services, sterile processing, OR, etc.) to communicate steam outages.
- Schedule regular maintenance of equipment, document preventive maintenance, and document repairs.
- Monitor pressure of supplied steam; follow established policy and procedure if corrective action (e.g., valving correction) is required.
- Recognize steam spraying on filters or other malfunctions that can cause mold growth; correct the condition and follow the established remediation protocols.
- Label steam lines and incorporate potential burn hazard awareness and methods to safely work with steam in MAE education and training programs.

(See also **31. Cleaning, Disinfection, and Sterilization**; **83 Food-borne Illnesses**; **106 Sterile Processing**; **109 Nutrition Services**; and **114 Heating, Ventilation, and Air Conditioning**.)

Maintain and repair refrigerators and freezers[7,8,81]

Risks

- Inadequate refrigeration of foods may permit growth of microbes, resulting in a greater likelihood of foodborne illness.
- Inadequate refrigeration of medications, biologics, vaccines, blood, and blood products may alter potency and/or chemical composition or allow proliferation of microbial contaminants.
- Condensate pans for refrigerators and/or freezers used to store food, pharmaceuticals, and blood products can create conditions for mold growth.

Interventions

- When selecting/purchasing equipment for cooling or freezing, compare features that best meet the intended use, including operating range (e.g., an automatic defrost cycle can damage temperature-sensitive items), size, location of use, cleanable surfaces, durability, and maintenance needs.
- Provide accurate temperature monitoring for refrigerators and freezers; an alarm system may be required (e.g., blood bank refrigerator) or desired.
- Establish a method to record temperature on a regular basis (e.g., visualize and document daily or observe an automated recording chart each shift); include action to take if reading is not in the acceptable range.
- Schedule routine monitoring and testing of refrigerator and freezer alarms where applicable.
- Test accuracy of thermometers; calibration may be required (e.g., blood bank, tissue freezer) by using standard regulations and/or recommendations.
- Schedule and perform regular preventive maintenance of all freezers and refrigerators; include air vents, gaskets, cooling coils, and fans.

- Walk-in refrigeration units may experience a condensation point if the building dehumidification is inadequate, resulting in mold proliferation.
- Provide training for personnel in recognizing and implementing safe maintenance of refrigerators to include appropriate cleaning methods.

(See also **23. The Immunocompromised Host**; **83 Food-borne Illnesses**; **109 Nutrition Services**; **110 Pharmacy Services**; and **119 Emergency Management**.)

Maintain and repair of exhaust and vacuum systems[1,7,15,16,35,43,46,71,49,53,57,59,62,77]

Risks

- Inappropriate placement of exhaust vents in the proximity of air or gas intakes creates a potential for reintroduction of hazardous vapors, gases, aerosols, odors, particulates, and/or microbes.
- Smoke-plume control systems may be unable to remove environmental tissue smoke during surgical procedures.
- Malfunction of a medicated aerosol control booth, hood, or induction chamber can cause airborne medication (e.g., pentamidine) leakage and/or allow escape of droplet nuclei (e.g., containing *Mycobacterium tuberculosis*) during patient treatment.
- Overflow of contaminated secretions into clinical vacuum systems contaminates the vacuum controls and/or wall lines.

Interventions

- Design and install exhaust vents in appropriate locations or move them a recommended distance from air and gas intakes.[1]Label exhaust systems that may contain infectious or hazardous airflows according to local code requirements.
- Maintain overflow traps on suction apparatuses.
- Perform routine maintenance on a regular schedule (e.g., for HEPA filter capture systems using 99.97 percent efficient filters for 0.3-µm particles; conduct a filter certification periodically and when filters are changed).
- Routinely evaluate air velocity at the opening of capture devices and adjust as needed to ensure that operational specification is met; adjustable fronts on cabinets, in-cabinet equipment and supplies placement, heat-generating devices (e.g., needle/loop benchtop incinerator or gas-generated flame), and location of operator can adversely affect performance.
- Decontaminate biologic safety cabinets before maintaining or repairing them; only persons trained in decontamination of hoods/cabinets should perform maintenance or repair.
- Wash hands after manipulating or changing vacuum controls.
- Wear appropriate PPE if exposure to blood/body fluids or other hazards is anticipated.
- Notify appropriate personnel (e.g., lab, operating room, infection control) in advance of any planned maintenance or outage of vacuum or vapor capture systems.
- Plan for meeting equipment and service needs in case of unplanned loss of these utilities (e.g., portable suction machines, relocation of activities). Know the restoration procedure, including verification for return to service.

(See also **67. Respiratory Care Services**; **108 Laboratory Services**; **116 Construction and Renovation**; and **119 Emergency Management**.)

Maintain and repair of medical gas delivery systems[1,15]

Risks

- Condensation of water in medical gas system lines has the potential for transmitting microbes within the piping system directly to patients.
- Unfiltered air or other gases may expose the patient to opportunistic microbes.
- Debris may become dislodged during gas interruptions and repair and from vibrations or other disturbances.

Interventions

- Evaluate design/redesign of medical gas systems when planning renovation or construction projects.
- Install filters and air to prevent condensation in medical gas system lines. Maintain dew points within regulatory ranges.[15]
- Wash hands before and after maintenance or repair procedures.
- Install and maintain the gas distribution system according to code requirements.[15]The installation should include filtration of the product gas, especially medical air and oxygen.
- Provide filtration and/or pressure limit as appropriate to protect medical devices used for respiratory therapy.
- Anticipate and react to capture debris dislodged from interruptions, repairs, or other disturbances to the system.

(See also **67. Respiratory Care Services**; **68 Surgical Services**; **108 Laboratory Services**; **116 Construction and Renovation**; and **119 Emergency Management**.)

Maintain and repair waste processing systems including incinerators, autoclaves, trash chutes, dumpsters, and compactors[1,7,9,10,13,22,37,38,59,95,96,97,98,99]

Risks

- Inadequate containment, transport, storage, and disposal of hazardous and/or regulated medical waste have the potential to contaminate personnel, the facility, and the external environment.
- Improper venting of chutes and compactors may spread microbes and odors to the surrounding areas.
- Riser effect from thermal currents moves particulates and odors upward through elevator shafts, etc.
- Improper containment and/or storage of waste or recyclables (e.g., soda bottles, glass jars, food cans) may result in insect or vermin infestation.
- Transport bins, carts, or vehicles may become contaminated from leakage due to poor integrity, spillage from tipping, or exterior container contamination.
- Improper sorting and containment of waste at point of creation can pose a risk for waste handlers "downstream" (e.g., sharps, laboratory cultures, radioactive treatments from nuclear medicine, pharmaceutical, and chemotherapy wastes).

Interventions

- Review design and locations of areas related to waste (e.g., soiled utility rooms, locations for sharps containers, recycling container locations, temporary storage areas, routes for transporting, chutes, ventilation in storage areas, security, etc.) when planning for renovation or construction projects.
- Provide pest control with approved methods to prevent future vermin infestation.
- Develop procedures for proper containment (e.g., bagging, boxing, container type, and labels and color-coding) of wastes as appropriate to type, composition, and volume generated. Ensure that appropriate personnel receive continuing education related to these procedures as well as require safety procedure (PPE and hand hygiene).
- Instruct personnel in the proper operation of equipment and recognition of malfunctions requiring immediate action and/or repair.
- Develop and follow procedures related to the safety and security of waste storage areas; improve as indicated (e.g., restrict access and ensure that chutes contain good seals and operational latches, appropriate sorting, correct containerization, cleanliness) in compliance with codes and regulations.
- Do not compact biologic, chemical, radioactive, or other hazardous wastes.
- Provide training that includes response to chemical, biologic, or other hazardous waste spills.
- Develop and follow procedures for recycling (e.g., beverage or food cans), including rinsing and time limits for storage; evaluate the arrangement and ensure that it is working (e.g., no complaints of odor or evidence of insects).

(See also **108. Laboratory Services**; **113 Waste Management**; and **119 Emergency Management**.)

Maintain and repair ice makers[7,8,82,86,88]

Risks

- Condensers and ice holding bins can become contaminated, which may result in transmission of microbes to susceptible individuals.
- When ice makers are nonfunctional, tubs or basins are used to hold and carry ice, which increases probability of contamination.
- Lack of routine maintenance can increase scale/biofilm buildup in lines. This may protect or enhance microbial growth.
- Interruption or outage of potable water supply increases risk of line or ice maker contamination once water is restored.
- Improper drainage configuration may lead to back-siphon, resulting in contamination of components and subsequent contamination of ice.
- Leaks and improper drainage around ice machines can cause wall and floor damage and subsequent mold growth.

Interventions

- Select equipment that is appropriate for location, ice demand, and design and that minimizes risk of contamination (e.g., dispenser preferred over bin).
- Perform regular preventive maintenance, including cleaning condensers, flushing and descaling lines, and cleaning and disinfecting bins per manufacturer's instructions.

- Provide timely repair of nonfunctioning equipment. Consider equipment replacement if repairs cannot be made quickly.
- Educate users in obtaining ice without contaminating equipment or stored ice; consider restricting access to authorized/trained personnel.
- If patient and/or visitors are allowed to obtain ice, include instructions on procedures to minimize contamination.
- Include provisions for alternative ice source(s), including methods for safe storage, transport, and handling in case of outage.
- For anticipated or unplanned outage, include a plan to shut off equipment (e.g., turn off water supply) and ensure safe return to service once supply is restored.
- Provide integral water-resistant flooring around drains to help prevent mold growth.

(See also **23. The Immunocompromised Host**; **27 Hand Hygiene**; **70 Biofilm**; **77 Environmental Gram-negative Bacilli**; **84 *Legionella pneumophila***; **95 Tuberculosis and Other Mycobacteria**; **115 Water Systems Issues and Prevention of Waterborne Infectious Diseases in Healthcare Facilities**; **116 Construction and Renovation**; and **119 Emergency Management**.)

Maintain transport systems in the hospital[1,7,19,66]

Risks

- Blood/body fluid (e.g., from specimens due to spill or leak) may contaminate transport system pathway (e.g., pneumatic tube system), receiver station, transport cart, dumbwaiter, or elevator.
- Disruption caused by such spills can delay specimen transport and processing until the area is cleaned and disinfected.
- Workers may be exposed to bloodborne pathogens, other microbes (e.g., sputum specimen, tissue specimen), or chemicals (pharmaceuticals; preservatives such as formaldehyde).
- A specimen or medication may be lost due to a spill or leak and cause a delay in diagnosis or treatment.

Interventions

- Choose a system that best meets needs while minimizing risks (e.g., location of stations; capacity, complexity, safety of secondary containers that enclose and protect/pad; ability to access; easy to clean and disinfect).
- Train personnel in the appropriate methods and equipment to use when preparing, containing, and transporting items (e.g., specimens or medications).
- Develop and follow procedures designed to minimize risks in the advent of a spill within the pneumatic tube system.
- Consider pneumatic tube system (PTS) carrier options (leak resistant with O-rings) and packaging strategies (i.e., double-bagging) to minimize the risks of leaks within the system.
- Establish methods and communication protocols to recognize spills or leaks; include communication protocol (e.g., notification to sender, system shutdown, and alternative methods of transport), cleaning and decontamination, retrieval of "stuck" items, and restoration of system.
- Include training related to selecting and using the appropriate PPE and hand hygiene for those working on the transport system.

- If patterns of misuse are noted, consider collaboration with users to improve safe use of transport system (e.g., performance improvement activity).

(See also **27. Hand Hygiene**; **100 Occupational Health**; **108 Laboratory Services**; **110 Pharmacy Services**; and **119 Emergency Management**.)

Anticipate and plan for continuation of services during outages and disasters[1,4,7,13,17,29,32,50,41,56,81]

Risks

- Loss of one or more utilities can compromise ability to safely maintain some or all services.
- Electrical outage or brownout may cause disruptions that may not be sufficiently handled by the backup emergency electrical supply or generators.
- Electrical disruption may adversely affect systems and equipment operation or the availability of emergency electrical supply to meet all needs (e.g., tripping of breakers, automatic shutoff, disruption of communications or information technology services, insufficient outlets for needs, HVAC, refrigeration, heating and cooling capacity).
- Lack of critical ventilation for AIIR, PE, and procedure areas pose a hazard to patients, workers, and visitors.
- Portable air filtration devices may be put into use without verifying appropriate type, size, operation parameters, or placement. This can create the potential for inefficient filtration, redirection of airflow, or imbalance of pressurization. Appreciably, malfunctioning units may be tampered with by patients, visitors, or staff due to noise or location within a setting.
- Water supply disruption (e.g., outage, line breakage, boil water advisory, low pressure) can affect many aspects of providing safe care, including but not limited to, hand washing, bathing, drinking, making ice, cooking and dishwashing, laundry, equipment or procedures that depend on potable water supply (e.g., making purified water for hemodialysis, cleaning and reprocessing of instruments, radiology and laboratory procedures), flushing toilets and clinical sinks, generation of steam, and humidification.
- Loss of sewer facilities may pose risks (e.g., full or overflowing toilets, no opportunity for disposal of wastes from bedpans, loss of drainage from sinks, tubs, and showers).
- Loss of one or more medical gases may cause imminent danger or interfere with provision of services (e.g., failure of life-support equipment such as ventilators may cause breathing and/or cardiovascular distress in some patients) or result in cancellation or delays in surgeries.

Interventions

- Plan for emergencies. Plans should address probability, impact (people, property, and business), preparedness, and internal/external responses.
- Perform a hazard vulnerability analysis to help identify equipment, supplies, utilities, and other resources that may be affected by various disasters (technologic events, natural or manmade disasters, human error, hazardous materials).
- Develop system failure contingency plans for essential utility systems.[13]
- Provide training and drills that include scenarios related to utility loss to test emergency preparedness and response.

- Coordinate provision of alternatives (e.g., evaluation of emergency electrical outlets, plan for negative pressure ventilation loss for AIIR, alternative supply of potable water and ice, alternatives to hand washing, obtaining portable toilets, switching to portable oxygen tanks).
- If portable air filtration units are part of the emergency filtration plan, determine the proper type, size, operation parameters, placement in rooms of anticipated use, and establish educational needs (e.g., instructions for patient and staff on proper placement and use); if the setup includes redirection of filtered air (e.g., vented out through window), ensure that emergency plan addresses how to keep venting areas sealed.
- Plan for safe restoration of utilities or equipment.
- Use an incident command or similar team structure to make decisions on limiting services, procedures, visitors, admissions, and the need for partial or full evacuation. Include infection prevention where appropriate.
- Document drills and real events. Collect information from those involved in drills or real events and analyze data to improve preparedness and response.

Methods to Help Identify Risks and Apply Performance Improvement

There are several tools that can be utilized to improve safety for workers and patients alike.[7,12,13,17,23,26,29,30,39,40,41,42](See also **16. Quality Concepts**, and **17 Performance Measures**.)

Root Cause Analysis

A root cause analysis (RCA) can be a powerful tool when investigating an event or near miss that could result in morbidity or mortality. The goal of an RCA is to determine what happened, why it happened, and what can be done to prevent recurrence. During an RCA, basic and contributing causes are discovered by continually digging deeper, by asking "why?" at each level of cause and effect. The process is interdisciplinary and involves experts from the frontline or those most familiar with the situation. The process is impartial and helps identify changes that need to be made. A credible RCA must involve leadership, be internally consistent, and include consideration of relevant literature and resources. To be effective and thorough, it must include a determination of all factors, including human: a determination of related processes and systems with analysis of underlying cause-and-effect systems, an identification of risks and their potential contributions, and a determination of potential improvement in processes or systems.

Failure Mode and Effects Analysis

As with RCA, the failure mode and effects analysis (FMEA) is a collaborative tool or technique that helps determine which interventions or corrections may reduce the risk of an adverse event. Unlike the RCA, the FMEA is prospective; it uses a streamlined hazard analysis to identify processes and subprocesses and then determine where or in what modes they may fail. Steps in FMEA include (1) define a topic with clear definition of process to be studied; (2) assemble a team; (3) graphically describe the process; (4) conduct a hazard analysis, including listing and numbering of all potential failure modes, determine severity and probability of each, use a decision tree to analyze for further

action, and list all causes for each mode; and (5) determine actions (eliminate, control, or accept) for each failure mode, describe the actions, identify outcome measures to evaluate the modified process, identify the individual(s) who will complete the recommended action, and indicate administrative concurrence.

Plan, Do, Check, Act

The four-step process of plan, do, check, act (PDCA) is easily applicable to a variety of activities. The origin of PDCA is sometimes called the Shewhart or Deming cycle, named after the inventor and subsequent prominent user, respectively. The PDCA tool may be preceded by use of the FOCUS tool. The acronym FOCUS represents finding a process to improve, organizing to improve the process, clarifying current knowledge of the process, understanding sources of process variation, and selecting the process improvement. Once a process is identified, the cycle proceeds as follows: plan the improvement and data collection process, do the improvement and data collection, check the results of the implementation, and act to hold the gain and continue or to reject and start another cycle. An example of using PDCA could be to evaluate and improve the process of education and control measures during construction activities.

Infection Control Risk Assessment, Infection Control Risk Mitigation Recommendations

The process of assessing infection control-related risks and developing risk mitigation recommendations and strategies is one that can and should be applied whenever there is a question about the most appropriate actions to be taken about any activity that has an infection risk. Critical to the process is appropriate participants, a clear understanding of the population that may be at risk, and a clear understanding of the activity being considered. After careful consideration of the activities and potential risks, a risk mitigation plan can be developed, documented, and followed. Often, control points are identified and control measures created to be measured against.

Conclusions

MAE partnership with IPs and safety personnel is essential to identifying and decreasing risks in healthcare settings. Facility and utility components, equipment, and related surroundings that are not managed appropriately may transmit infectious microbes or pose other hazards that threaten the safety of people, buildings, and the community. Regardless of setting, size, and scope of service, identifying the standard elements with collaborative risk assessment and applying appropriate interventions will reduce or eliminate these hazards. Infection prevention and MAE staff also need to work collaboratively to develop and maintain effective communication and education programs to minimize risks.

Future Trends

Use of newer methods, such as computational fluid dynamics and other technologies to broaden our understanding of particulate and bioaerosol behavior, in addition to applying interventional strategies, will help to define and improve the design and operation parameters of mechanical systems within healthcare settings. The use of different materials in our ventilation and water distribution systems has contributed to more corrosion-resistant and more maintenance-friendly equipment. The design and construction of air handling units and cooling towers have improved dramatically in the past decade and continue to improve; this will work to minimize risks. Our understanding and implementation of risk assessment processes have also grown, and continued growth and improvement can be expected.

Challenges, including budgetary constraints and environmental stewardship, will help to shape healthcare across all settings. The trending of an aging population, coupled with emerging infectious agents and globalization, will be important considerations for the future of patient and worker safety. Regulations, recommendations, and guidelines by authoritative agencies and professional organizations continue to align and refine the relationship between people and the healthcare environment. Further research that applies evidence-based weighting and consideration for each unique setting will enhance our understanding of this evolving industry we call healthcare services.

International Perspective

Healthcare settings vary from country to country and within political boundaries. They are shaped by cultural and economic variations and can be further modified by geographical locale. Each facility has unique challenges and resources to address structure, utilities, equipment, and location parameters related to maintenance and engineering. The IP and MAE should act as a team. They should use community standards to determine the best practices but also look to international studies and best practices for evaluation and/or consideration. They must use the available resources, applicable regulations and recommendations, and available administrative support, regardless of location, to protect the health and safety of all.

Declarations of Conflicts of Interest: William Pate was elected board member for the South Texas Chapter of the Health Physics Society through April 2014. He is also employed by The University of Texas Medical Branch as an Environmental Health and Safety Consultant.

Abstract

The infection preventionist has varying levels of involvement with healthcare waste management and is often focused on regulated medical waste. An effective waste management program is complex due to numerous regulations and guidelines, evolving technologies, expanding healthcare delivery settings, emerging infectious diseases, and the potential for bioterrorism. Although responsibility for the management of healthcare waste is typically outside the area of responsibility for most infection preventionists, they may still be included in a wide range of areas related to management of healthcare wastes beyond the traditional role. This chapter provides information and resources to assist the infection preventionist with successful participation in the safe management of healthcare wastes.

Key Concepts

- Definitions of medical waste can be confusing.
- Medical waste regulations and guidance should be based on scientific analysis.
- Waste management plans should include input from the infection prevention and control program.
- The infection preventionist should be aware of new technology and emerging issues related to healthcare wastes.
- Performance improvement may be used to measure effectiveness of waste management.

- International positions for managing healthcare wastes vary considerably based on country-specific regulatory requirements and definitions.

Background

In the late 1980s and early 1990s, medical waste caught the public's attention because of its potential for environmental contamination and disease transmission. Media sensationalism focusing on beach wash-ups and dwindling landfill space combined with fears regarding human immunodeficiency virus (HIV) transmission resulted in emotional reaction and confusion that was not based on scientific analysis.[1,2,3,4]

When asked to define the risks that healthcare wastes pose to the public and to the community, experts at the Centers for Disease Control and Prevention (CDC) stated: "There is no epidemiologic evidence to suggest that most hospital waste is any more infectious than residential waste. Moreover, there is no epidemiologic evidence that hospital waste disposal practices have caused disease in the community; therefore, identifying wastes for which special precautions are indicated is largely a matter of judgment about the relative risks of disease transmission."[5]Although this statement was originally prepared in 1985, it was restated for inclusion in the CDC's *2003 Guidelines for Environmental Infection Control in Health-Care Facilities*.[6]Although there is no documented evidence of transmission of disease to the public through healthcare waste streams, data limitations prevent firm conclusions on risk from being developed.[4]

Unfortunately, some confusion remains, compounded by inconsistent, specific, and occasionally conflicting definitions of "medical waste" or "infectious waste." This is promoted by input from individuals with little knowledge of infectious disease transmission or related microbiology. Documents have been drafted at local, state, and federal levels that lack scientific risk/benefit analysis.[1,3,6]

Hospitals and other healthcare settings have recognized the potential occupational risk of disease transmission and therefore use caution when handling and disposing of wastes.[7]Healthcare "infectious" wastes may include microbiological laboratory waste, hazardous waste, blood/body fluids, sharps, pathology wastes, pharmaceutical wastes, and certain wastes from patients who are placed in isolation.[4] Careful handling, sorting, and transportation, as well as appropriate packaging and disposal of waste from these settings may help to explain the absence of transmission in the community.

This chapter discusses healthcare waste from a practical and scientific perspective, with the majority of the chapter focusing on traditional "infectious" waste. However, the infection preventionist (IP) may be involved in other aspects related to waste management in a variety of healthcare settings. These selected issues include purchasing, design of waste disposal areas, reuse and recycling (including increasing popularity of reusable sharps disposal containers), handling and disposal of special types of waste (bacillus Calmette-Guérin [BCG], gene therapy, probiotics, piped systems waste, mixed wastes, chemotherapeutics, radioactive materials, and emerging infectious and bioterrorism agents), waste disinfection and sterilization technologies, ecological considerations, and assessment of a waste management plan using performance improvement. Accordingly, brief and pragmatic overviews of varied waste topics are included to assist the IP, and resources are provided for further consideration. Individual healthcare facilities and services must consider applicable codes, regulations, and guidelines prior to implementing or updating an effective waste management program.

Basic Principles

Waste-related Regulation and Guidance

On the federal level in the United States, several agencies have published regulations pertaining to "infectious," "medical," or "regulated" waste. The U.S. Environmental Protection Agency (EPA), the U.S. Occupational Safety and Health Administration (OSHA), and the U.S. Department of Transportation (DOT) have such regulations.[8,9,10,11,12] In addition, both the CDC and EPA have issued guidance documents pertaining to medical waste management.[5,6,12,13] At the request of the U.S. Congress, the Agency for Toxic Substances and Disease Registry prepared and published a comprehensive review of the public health implications of medical waste.[14]

The Joint Commission includes medical waste as hazardous within its Environment of Care standards through several elements of performance (EP) within EC.02.01.01 and in EP 6 under Infection Prevention and Control in standard IC.02.01.01.[9] The U.S. Postal Service has laws related to sending hazardous and biological substances through the mail.[14] The Nuclear Regulatory Commission has jurisdiction over waste that contains both biological and radiological hazards ("mixed waste").[15] The U.S. Food and Drug Administration's Center for Devices and Radiological Health has regulatory authority over selected aspects of waste management, including the designation of sharps disposal boxes as class II medical devices.[16]

Other agencies have regulations and guidelines related to wastes from healthcare settings; selected entities are identified where indicated in the chapter. (Also refer to **4. Accrediting and Regulatory Agencies**.) In the United States, various state and local governments have a range of regulations related to these materials. Therefore, it is important that IPs recognize which regulations are applicable based on the authority having jurisdiction for their healthcare setting(s). IPs should remain current with applicable state and federal regulatory activity within the United States or with the authority having jurisdiction for regulatory oversight in the international community.

Waste Terminology

The primary constituent of healthcare waste that is traditionally of interest to IPs is waste capable of transmitting infectious agents. Articles on this topic offer inconsistent findings due to lack of a standardized definition of what constitutes waste capable of transmitting an infectious disease.[13] Terms such as "biomedical waste," "regulated waste," "red bag waste," "medical waste," and "infectious waste" have been used interchangeably. The same term may have a different definition depending on the resource. For example, in a background paper, the Office of Technology Assessment defined "medical waste" as "all the types of wastes produced by hospitals, clinics, doctors' offices, and other medical and research facilities. These wastes include infectious or 'red bag' hospital wastes, hazardous (including radioactive) wastes and any other general wastes."[17] In the Medical Waste Tracking Act of 1988, "medical waste" was defined as "any solid waste which is generated in the diagnosis, treatment or immunization of human beings or animals, in research pertaining thereto, or in the production or testing of biologicals."[18] Categories of waste that are included in these definitions vary from state to state and even from federal agency to federal agency.[3,6,8,10,11,13,19] To reduce confusion, the term "infectious waste" is used here to refer to "waste that is capable of producing an infectious disease."

A common misconception is to assume that the presence of a pathogen will result in infection from wastes. Pathogenic organisms are found in many different day-to-day settings. Household garbage, bed linens, soiled diapers, and unwashed hands are all examples of environments in which pathogens can routinely be found both within and outside the healthcare setting.[3,6,13] A number of studies have shown that although hospital wastes can have a greater variety of organisms than residential wastes, those from households are more heavily contaminated.[6,13] Even when generated from healthcare activities, most garbage, soiled bed linens, and diapers do not have any special handling requirements in most instances.[6] For a waste to be capable of causing infection, the following specific factors are necessary: (1) dose, (2) host susceptibility, (3) presence of a pathogen, (4) virulence of a pathogen, and (5) portal of entry. Concisely, all five of these factors must be present for infection to occur from waste.[3]

Infectious Waste Categories

Many categories of infectious waste have been proposed by a variety of associations, individuals, and agencies in the past.[3,6,13,17,19] However, if the preceding definition is strictly adhered to, developing categories of infectious waste is fairly simple and should include the following.

Contaminated Sharps

All discarded sharps (e.g., needles, scalpels) that have come into contact with potentially infectious materials should be considered infectious waste. This category of infectious waste poses the greatest risk for injuries.[3,6,8,13,20] The risk of infection is related to contamination with a sufficient dose of pathogenic organisms (such as Hepatitis B virus [HBV], Hepatitis C virus [HCV], or HIV) and the provision of a portal of entry into a susceptible host via a puncture or cut. These devices represent a significant occupational hazard to those handling and disposing of them. However, once contaminated sharps are properly placed into appropriate rigid, puncture-resistant containers, the environmental risk they pose is negligible.[1,2,3,6,8,13,21,22,23,24] (Also see **105. Minimizing Exposure to Blood and Body Fluids**.)

Microbiologic Cultures and Stocks of Infectious Agents

Of all of the possible categories of infectious waste, untreated cultures, stocks, and amplified microbial populations pose the greatest potential for infectious disease transmission because they contain high concentrations of potentially pathogenic organisms.[6,21,22] Laboratory personnel should handle discarded cultures and stocks accordingly.[22,23] Cultures and stocks may be stored in glass containers (e.g., tubes) that, if broken, become contaminated sharps and therefore should be handled carefully. Microbiologic waste may be treated on-site prior to discarding (e.g., by autoclaving) and subsequently disposed as nonhazardous solid waste in accordance with related solid-waste disposal regulations.[6,21,22]

Animal Wastes

Discarded material originating from animals inoculated with infectious agents during research, production of biologicals, or pharmaceutical testing should be considered infectious waste.[21] These materials are similar to microbiologic cultures and stocks because they may contain high concentrations of pathogenic organisms. Therefore, animal wastes that fit into this category are handled in the same manner. Certain tissues and bodies from animal research areas may have special considerations for handling and

disposal dependent on potential for zoonotic microbes; each should be addressed based on knowledge of the specific organism.[6,21]

Blood and Blood Products

Blood and blood products, as defined in the OSHA Bloodborne Pathogens standard (e.g., serum, plasma, and other components known or suspected to be contaminated with a transmissible agent) must be handled carefully. Small amounts of these materials dried on dressings or other disposable items represent an insignificant hazard once they are properly contained because of the absence of a portal of entry and a means of transmission.[8]Bulk blood, blood-tinged suctioned fluids, excretions, and secretions are considered infectious waste because they may be splashed onto mucous membranes or because the container may break and become a contaminated sharp. These fluids may be carefully poured down a drain connected to a sanitary sewer that is designed for the disposal of human waste.[6]

Before disposing of these fluids in the sanitary sewer, it is important to verify that local regulations allow this practice, as there may be local prohibitions on the disposal of whole blood in the sanitary sewer. Personnel must follow Universal/Standard Precautions, including the use of personal protective equipment (PPE), due to splash and aerosolization potential.[6,8]Alternative treatment methods for inactivation or handling prior to disposal are available.

Selected Isolation Wastes

Discarded waste materials contaminated with excretions, exudates, and secretions from patients with highly communicable diseases (classification 4 by the CDC in *Classification of Etiologic Agents on the Basis of Hazard*, e.g., Ebola) treated in isolation should be classified as infectious waste.[21]Blood and sharps originating from these patients are already included in the preceding categories.

Pathology Wastes

Pathology wastes include human tissues and body parts that are collected at autopsy or during surgery. Pathology wastes do not usually fit the definition of infectious waste outlined previously. There is an absence of a portal of entry and most of these materials have been soaked in alcohol or formaldehyde and thus seldom contain pathogens. Incineration or grinding and discharging into a sanitary sewer are the common acceptable methods of treating this waste.[6,8,22]

Nonincluded Wastes

Other categories of infectious waste have been suggested even though there is no scientific justification for their inclusion.[13,17]Personnel who are responsible for developing safe handling and disposal practices for these materials must keep in mind that the waste discharged from healthcare institutions differs little from that in normal households.[6,13,17]Most persons with infectious diseases are not hospitalized. Thus, characterizing all waste as infectious increases healthcare costs and creates undue confusion and concern.[3,5,6,13,20]

Waste Management Plan

Plan Basics

The efficient waste management plan addresses every step from acquiring materials that become waste to generation of waste, discarding, collection and containment, handling, accumulation and storage, transportation, treatment, and ultimate disposal.[6,13] The key to success is a collaborative effort, including the IP's involvement.

Infectious Waste

Once a facility has a working definition of "infectious waste," the next step is to develop or update a plan for managing these materials. A management plan is addressed to some extent by regulatory, advisory, and licensing agencies such as OSHA and the CDC, various state agencies such as the Department of Natural Resources or Department of Health, as well as other bodies, such as The Joint Commission.[5,6,8,9] This written plan should include provisions for the assignment of responsibility and authority for overseeing the program to an individual, such as the IP or the facility safety officer, who is knowledgeable regarding infectious disease transmission and who is familiar with applicable federal, state, and local regulations. This will ensure that these materials are handled as required and in a scientific manner. Objectives for the plan include (1) rendering infectious waste safe for disposal; (2) ensuring that there is minimal risk to patients, personnel, visitors, and the community from exposure to pathogenic organisms associated with waste generated in the healthcare facility; (3) meeting or exceeding all federal, state, and local regulations; and (4) educating the healthcare personnel regarding the management plan and the real versus the perceived risk associated with "infectious waste." For example, the effective application of a facility-wide medical waste assessment and management plan resulted in a 58 percent reduction in volume of waste designated as medical at one facility.[25]

The other components of an "infectious waste" management plan include (1) designation, (2) segregation, (3) packaging, (4) storage, (5) transport, (6) treatment or disposal, (7) contingency planning, and (8) staff training.[8,10,26] Each component is discussed further in the following sections.

Designation

Once a facility has developed definitions for infectious and noninfectious wastes, sorting the discarded materials into the proper waste stream should align with regulatory, safety, and cost-reduction facets.[10,26] It is recommended that a list of infectious wastes generated in the facility be developed and that the generating areas be identified in the management plan. For example, blood/blood products known or suspected to be infected with transmissible agents are generated on patient floors and in surgery, the autopsy suite, clinics, emergency rooms, and ancillary departments.

Segregation

Individuals who are knowledgeable about the waste's origin and its hazard potential must segregate infectious waste at the point of origin.[13,17,19,26,27] The waste should then be placed into appropriate designated leakproof containers. Needles must never be recapped, bent, or broken by hand before being discarded. Infectious waste with multiple hazards (e.g., used sharps from patient receiving chemotherapy) must be segregated as necessary for the management and treatment of the waste characteristic with the most stringent handling requirements. For example, proper segregation of waste generated in the surgical suite can limit the volume to that which meets definitions of infectious waste if perioperative personnel can be engaged in separation at this point of use. Examples of successful segregation in this setting have been described that also offer benefits of environmental sustainability

and facilitate recycling of the large quantity of materials and packaging generated during perioperative care.[28]

Packaging

Infectious waste must be packaged properly to protect patients, staff, visitors, and the public from potential exposure to infectious materials and to facilitate the proper handling, storage, treatment, or disposal of the waste.[5,6,8,10,13,29,30] Selection of the packaging must be appropriate for the type of waste being contained to maintain the integrity of the packaging during collection, transport, storage, and disposal. States generally specify packaging requirements in their infectious waste regulations. In addition, OSHA and the CDC specify that sharps be placed in rigid puncture-proof containers.[5,6,8]

Infectious waste must be properly identified as a biohazard. Infectious waste containers should be labeled with a biohazard label or color-coded red to identify the contents. OSHA requires either red color-coding or use of the universal biohazard symbol and term "biohazard."[8,22] State regulations may require additional information on the packaging, such as the name of the generating facility, date, bilingual terminology, and so forth. Packaging used for shipment will often contain additional markings and be labeled to comply with applicable shipping regulations (e.g., orientation arrows on sharps containers).

Sharps containers must be impervious, rigid, puncture resistant, leakproof on the sides and bottom, and closable.[6,24,31] Plastic bags are appropriate for bulk solid or semisolid infectious wastes or for disposables containing residual liquids. Plastic bags should be impervious and tear resistant. Potentially infectious liquid wastes can be carefully poured down a designated sanitary sewer using appropriate engineering controls and PPE.[6,8] When this is not desirable or possible, liquid wastes should be placed in leakproof containers, such as a flask or bottle, that can be tightly capped or stoppered. Absorbent material sufficient to absorb the entire contents of the containers must be added to the outer container. Free-flowing liquids should not be poured directly into a waste container. Suction canisters must be tightly closed and placed in plastic bags. Bags may need to then be placed in a secondary container, such as a cardboard box, to preserve the integrity of the packaging during transport and storage. Semirigid or rigid secondary containers usually are required for off-site transport of infectious waste.[8,29]

Storage

Infectious waste should be treated and disposed of as soon as possible after generation.[5,6,17,19,26,29,30]

Although there is no published national standard for how long infectious waste may be stored, some states may have limits on storage time at the generating facility. The proper packaging outlined here will ensure containment and exclusion of rodents and vermin. Storage areas should have limited access, and a biohazard symbol should be posted so it is readily visible to anyone with access to the area. Many states have specifications for the type of enclosure required for storage of infectious waste, and they often specify the duration of storage that is permissible. Some states have very elaborate requirements for storage areas that require the room to have floors that slope to a drain that is connected to a sanitary sewer. This provides for a safe method of cleaning up liquid spills. In any case, a system for immediate spill containment and cleanup should be available in the storage area (e.g., hose connected to steam line).

Transport

The internal and external systems used for the transportation of infectious waste must maintain the integrity of the packaging and protect handlers.[5,6,7,10,17,18,19,29,30] Mechanical waste collection devices and gravity or pneumatic-chute transport of infectious waste are discouraged due to potential damage to packaging. Leakproof carts that are readily cleanable or that can be lined with plastic are generally used for transportation of infectious waste from the generating areas to the storage area where it will be picked up for treatment. Commercial or private vehicles that are employed in the transport of infectious waste should be leakproof and identified in accordance with municipal, state, and federal regulations. IPs should be aware of regulatory requirements and provide input into relevant key operational services. For example, a facility's clinical laboratory couriers, who often pick up not only specimens but also infectious waste from affiliated physician practices and other ambulatory care facilities, commonly provide transport of infectious waste. In general, states require the registration of vehicles utilized in the transportation of infectious waste. Although some facilities will transport and treat their own infectious waste, appropriately licensed commercial companies may be contracted to transport and treat healthcare wastes.

A waste manifest documenting the shipment information must accompany transported waste. A waste manifest serves as a document that tracks the waste from the generating facility until its final disposition, and it acts as a record of the waste's movement. The waste manifest also acts as a legal document whereby the generator certifies that the waste has been correctly classified, packed, marked, and labeled according to applicable shipping regulations. Because of this, it is important that the waste manifest be reviewed and signed by a trained individual before the waste is transported off-site. The DOT considers the individual signing the waste manifest to be a hazardous materials employee, and thus the employer as required in 49 CFR must train them. Having the waste manifest signed by untrained employees can result in significant penalties. Copies of waste manifests must be retained for a minimum of 3 years under DOT regulations, although states can require longer retention time.

Treatment

Many options are available for the proper treatment of infectious waste.[2,6,10,13,14,17,21,30,31,32,33,34,35] The method selected will be determined by the amount of infectious waste generated, the capabilities of the facility, and the cost effectiveness of on-site treatment versus contracting the service to a licensed commercial vendor. The type of treatment selected will depend on municipal, state, and federal regulations. Incineration was traditionally selected by hospitals as the primary method for treating infectious waste but has decreased in application due to EPA regulations related to the Clean Air Act and control of emissions (also refer to Supplemental Resources). Depending on the type of infectious waste, acceptable methods for rendering these materials innocuous include steam sterilization, chemical disinfection, gas/vapor sterilization, and irradiation decontamination. Modern alternative technologies have broadened the scope of available treatment options. Microwave, infrared, hyperchlorination, and laser technologies are only a few of the new technologies being utilized to render infectious waste innocuous. The treatment selected should be based on the type of waste generated and the suitability of available options. States generally require that the efficacy of the treatment methods selected be monitored. The monitoring system selected will depend on the treatment method utilized. For example, steam sterilization treatment would be monitored utilizing a biological indicator that includes *Bacillus stearothermophilus* spores.

Disposal

The direct disposal of infectious waste at a properly sited landfill does not present a threat to public health and safety, according to many experts, and is still acceptable in many areas.[6,8,13] However,

perceived risk concerns and the nationwide movement away from land disposal have resulted in widespread landfill prohibitions on the disposal of untreated infectious waste in landfills. After treatment, medical wastes are usually disposed of in a sanitary landfill. Untreated liquid medical waste, such as bulk blood or the contents of suction containers, can be disposed of by carefully pouring them into the sanitary sewer when allowed by local regulations. When designing an infectious waste management plan, it may be helpful to communicate with the waste hauler contractor and local landfill representatives during the planning process. This will help ensure that the healthcare facility is in compliance with regulatory codes, and most importantly, it will help ensure education and training for those who handle and haul these materials.

Contingency Planning

Systems should be in place to address unforeseen events that may disrupt the normal treatment, transportation, and disposal of infectious waste materials.[10] Both on-site and off-site contingencies should be available. Alternate strategies should be available in case on-site treatment systems fail or if there is an unanticipated power shortage. A backup disposal contractor should be designated in case there is a disruption of the ability of the primary outside contractor to serve the facility. Emergency spill procedures should also be in place for on-site and off-site emergencies.

Training

Training of all personnel involved in the generation, handling, transporting, treatment, or disposal of infectious waste is imperative for the infectious waste management plan to be effective.[6'8'17'29'36'37]

Training should include the definition of infectious waste, handling procedures, appropriate PPE, hand hygiene, labeling or coding that designates an item as infectious waste, and postexposure management. There is also specific training required by regulatory agencies such as OSHA and the DOT. For example, individuals involved in the infectious waste shipping process (which includes signing of waste manifests), must meet DOT training requirements that includes at a minimum general awareness training, function-specific training, safety training, and security awareness training. As part of this training, the employee must be tested and the employer must certify in writing that the employee has met the training requirements. Training must be completed within 90 days of hire, with refresher training completed every 3 years. The employer must maintain records associated with worker training.

Infection Prevention Implications

The IP may be involved in developing and coordinating the infectious waste management plan. The plan should be based on sound scientific information and consistent with local, state, and federal regulations and guidelines. An article by Rutala et al. contained noteworthy information related to medical waste that may be considered when developing or revising a healthcare waste management plan.[7]

- Hospitalized patients generate approximately 15 pounds of hospital waste per day, which averages to approximately 6,700 tons of daily waste by hospitals.
- About 15 percent of the total hospital waste by weight is considered "infectious waste" (1,000 tons/day).
- The cost of disposing of infectious waste is 5 to 20 times greater than that for disposal of noninfectious hospital wastes.
- With the exception of "sharps" such as needles, which have caused disease only in an occupational setting, there is no scientific evidence that medical waste has caused disease in the hospital or in the community.

- Household waste contains, on average, 100 times as many human pathogens as medical waste.
- The beach wash-ups of syringe-related materials that created nationwide concern were found to come from illegal drug use and home healthcare; hospitals were not implicated as the cause of this problem.

Other Waste Management Concerns

Purchasing

Products brought into healthcare settings and development of policies and procedures related to their use should be part of an effective infection prevention and control program.[28]Product selection should consider published recommendations and guidelines and comply with regulatory agency standards (e.g., sharps, disposal containers, or chemotherapy waste boxes).[5'6'8,9,10,11,12,13'15'16'36]Workers involved with handling of waste, such as used needles, should be included in an evaluation process.[8](Also see **105. Minimizing Exposure to Blood and Body Fluids**.) Waste minimization efforts, as part of a waste management plan, can be achieved by purchasing products that generate less waste or are substituted for existing items.

Waste Disposal Areas

Healthcare wastes of all types should be sorted at the point of creation. For example, used sharps should be immediately discarded into sharps disposal containers.[6'8'24]The design and construction of renovated or new healthcare facilities should include the IP in the process from conception through commissioning.[6'38'39]Waste handling and areas for storage and disposal should be designed and located as appropriate for the types of wastes generated by the facility.[39](Also see and **107 Environmental Services**.)

Waste Reduction, Including Reuse and Recycling

The IP may be asked to help evaluate reusable items to replace single-use, disposable items in an effort to reduce waste volume. (Also see **32. Reprocessing Single-Use Devices**.) Reusable containers for regulated medical waste and sharps disposal boxes are one such effort that has gained popularity with the increased emphasis on environmental stewardship. Some have raised concerns over safety of reusable sharps disposal containers in terms of adequate removal of potential contaminants after they are emptied, cleaned/disinfected, and returned to a facility.[12]Neely et al. compared recovery of surface contaminants from a disposable cardboard container with a plastic liner (note: this is not in compliance with OSHA-issued requirements for sharps containers) to a reusable plastic container.[40]The proportion and diversity of microbial contaminants on the reusable containers was higher; however, quantitative details (e.g. colony forming units) were not provided, and the majority of these contaminants were common skin commensals. Neely et al. compared the overall rate of healthcare-associated infection (HAI) before and after implementing a new policy of disinfecting the top of the reusable container and observed a statistically significant decrease; however, this study design could not account for a variety of other interventions that might account for this change. Runner cultured surfaces of reusable containers for bacteria and certain viruses delivered to a community hospital.[41]Quantitative levels of microbes recovered were not provided in the study and, as in the study by Neely et al., most of the bacteria were common skin commensals. Polymerase chain reaction (PCR) testing did identify a proportion positive for certain bloodborne viruses; however, PCR testing is very sensitive and does not

always correlate with presence of viable infectious virus. The IP needs to keep the findings of both studies in perspective relative to principles of disease transmission outlined in the Waste Terminology section of this chapter. Visible soil on or inside reusable containers should prompt notification of the manufacturer and not even be placed into use. Surface contaminants, even with bloodborne infectious agents, do not represent an appreciable risk to healthcare personnel given routine hygiene for hands and the environment typical of the hospital setting. Extensive studies of risk of occupational exposure to bloodborne infectious agents have indicated that the risk strata is highest for hollow-bore devices introduced through the skin, much lower for percutaneous introduction of blood/other potentially infectious material, and likely negligible for intact skin that is in contact with a contaminated surface. By contrast there is evidence that reusable sharps containers can dramatically lower the incidence of sharps injuries to healthcare personnel during disposal of contaminated sharps.[42]As described, the IP must be involved in the evaluation, selection, and implementation of a sharps disposal system, regardless of the container design that is chosen. A careful risk assessment should be completed to ensure that reprocessing of containers is effective and in compliance with regulations for the safety of patients and staff.[12]

Selected Special Types of Waste

Bladder Cancer Therapy with Bacillus Calmette-Guérin

Intravesical infusion of BCG to treat superficial bladder cancer was first reported in 1976 as an alternative to chemotherapy.[43]This immunotherapy was subsequently approved in 1990 by the FDA for use in the United States for carcinoma in situ, which is found in 20 to 30 percent of bladder cancer cases.[44]Intravesical administration of BCG appears to be associated with fewer adverse reactions, with influenza-like symptoms (including fever, chills and nausea) and discomfort as the most commonly reported.[44,45]However, there have been a few cases of localized and disseminated *Mycobacterium bovis*infections following infusion.[45]Treatments for bladder cancer that may be used with or without BCG include mitomycin C, thiotepa, doxorubicin, oral bropirimine, interferon alpha, keyhole limpet hemocyanin, and valrubicin.[46,47]

Little information is provided on infection prevention and the safe handling and subsequent disposal of items potentially contaminated with BCG. Although the *Mycobacterium*used for BCG is an attenuated strain, the amount of organism used for intravesical treatment is that of approximately 2,000 vaccinations.[48]Care must be taken to prevent introduction of BCG onto environmental surfaces or other items. A case of iatrogenic meningitis was reported in two immunocompromised children, presumably from contamination in the pharmacy cabinet where both chemotherapy and BCG to treat patients were prepared.[48]Control measures during BCG preparation include a combined transfer/mixing device that eliminates aerosols; the use of an applicator that connects to the catheter for infusion also prevents exposure. The entire setup should be discarded as potentially infectious waste.[49]Cleaning of potentially contaminated surfaces should be with a tuberculocidal-rated disinfectant (e.g., phenolic-based) per manufacturer's instructions. Recommendations in the United Kingdom by the Control of Substances Hazardous to Health (COSHH) regulations for worker protection include PPE (plastic apron, gloves, and face visor), disposal of materials and PPE as "clinical waste," and use of a phenolic-based disinfectant on potentially contaminated surfaces. COSHH also recommends that voided urine containing BCG be treated with a phenol-based liquid mixed in the toilet for at least 10 minutes before flushing.[49]An

alternative instruction to the patient after BCG bladder instillation is to "sit down to urinate for 6 hours after treatment to avoid splashing of the urine."[50]Directions state that after each urination "during this 6-hour period, pour household bleach (about the same amount of bleach as the amount of urine) into the toilet, then wait 15 minutes before flushing" and to wash hands afterward.[50]

Gene Therapy

As of May 2000 there were 425 gene therapy protocols worldwide, with approximately 70 percent of these in the United States.[51]Although human gene transfer and treatment had originally focused on genetic deficiency diseases, more than 60 percent of trials and activities since gene therapy products approved have been aimed at cancer.[52]The vectors used in gene therapy pose a potential infectious risk; for more than 3,100 patients treated, varied protocols were used for 177 retroviruses, 65 adenoviruses, 25 poxviruses, and 3 adeno-associated viruses. The remaining 109 treatments used lipofection and other noninfectious methods. Other vectors that have been proposed or used include Epstein-Barr, baculovirus, canarypox, fowlpox, herpes simplex, vesicular stomatitis, and HIV viruses.[52]

Information related to the safety of gene therapy in healthcare settings was introduced to most IPs in a 1999 article by Evans and Lesnaw.[53]The numerous recommendations included protection of healthcare personnel, other patients, and appropriate Transmission-based Precautions. These included suggestions that waste resulting from gene therapy be handled as biohazardous material and that disposal treatment should follow medical regulated waste protocols (i.e. incineration).[52]In some localities, regulations may require inactivation on-site prior to disposal.[53]

The U.S. Food and Drug Administrations' (FDA's) Center for Biologics Evaluation and Research regulates gene therapy research and trials with the objective to ensure safety.[54,55]The National Institutes of Health Recombinant DNA Advisory Committee provides protocol development oversight.[53,56]Federal supervision at the local level is by the Institutional Review Board and the Institutional Biosafety Committee, with optional input from the Infection Control Committee.[55]The CDC has not yet developed *infection prevention*guidelines for gene therapy.[54]The major goal for IPs is to prevent transmission of the vector or any recombinant vector between persons, including those handling and preparing the vectors (i.e., pharmacy). Therefore, the existing system recommended by the National Institutes of Health and CDC for biosafety levels and disinfectants should be referenced. Another concern is vector shedding that may occur inside and outside an isolation room from the treated patient, those caring for the patient, and others entering the patient's area, including housekeeping personnel. Protocols for safe transport of the vector product and items for disposal should be established and include training based on the vector and current knowledge of the vector.[53,54]Coordination with the waste disposal company may be required. If a healthcare facility is involved in gene therapy, the IP should be consulted and involved in policy and procedure development as well as education and training. Gene therapy and vectors are evolving, and the IP should follow current guidelines as appropriate to minimize potential risks related to handling and disposal. A biological safety officer position is suggested by some as a key member of any gene therapy trial team; the role includes ensuring appropriate handling of waste materials.[56]

Probiotics

Probiotics are beneficial and endogenous microflora that include live microbial supplements; they have been studied primarily for protection of the gut (e.g., *Lactobacillus*).[57,58]The use of probiotics continues to be explored in clinical settings. Probiotics may present side effects or risks for susceptible individuals, including infection, deleterious metabolic activity, excessive immune stimulation, and gene transfer; the latter three theoretic risks have not been reported in humans. The risk of infection is low, but cases have been observed, including fungemia with *Saccharomyces boulardii*and *Lactobacillus rhamnosus*.[59]

Regulation and guidelines for probiotics are limited, with concern related to inclusion as dietary/food or pharmaceutical applications.[60,61]Forms used in clinical settings may be a closed capsule or a sachet that is opened and combined with enteral nutrition or drink for ingestion.[59]Probiotic microbial supplements may be given alone or in combination with prebiotics, selected additives that may enhance survival of the probiotic strain while stimulating the body's endogenous flora.[58]Safe handling, management, and disposal of the probiotic are necessary to minimize the risk of infection. Selecting a safe place for preparation, dispensing or mixing, and disposal of associated waste materials is crucial to minimize infectious risks, especially for areas with immunocompromised patients.[59]

Piped Systems Waste

Vacuum and suction systems are part of the medical gas systems and should not be overlooked in a waste management program. The installers, inspectors, and verifiers should be certified based on codes and regulations.[62]Piped suction/vacuum systems and disposal of associated liquids are considered biohazardous. Such systems may be used for suction of body fluids in surgical and procedure areas, dentistry, laboratories, and research settings.[62,63,64]The waste holding tank, part of the piped vacuum system, should be installed per recommendations, with the waste tank contents discarded through a drain into the sanitary sewer system.[62]

Laser plume and surgical smoke may be evacuated into the wall suction system in some locations. Analysis of surgical smoke and aerosols has shown that viable organisms can be present, including bacteria and viruses, in addition to numerous potentially hazardous chemicals.[63,64,65]A case of patient-to-patient transmission of human papillomavirus has been reported during a laser procedure.[64]Use of wall suction, even with in-line filtration, is only suitable for minimal amounts of plume; a smoke evacuator system with appropriate filtration system is preferred. In both situations, the in-line filters from wall suction and plume capture equipment should be treated and discarded as potentially infectious waste.[63,64]

Plumbing systems, specifically sanitary sewers, are approved for disposal of small amounts of blood and body fluids, as mentioned, provided procedures are in place to protect the worker.[6,8]A concern over pharmaceutical wastes, specifically antibiotics entering the sewer system, has been raised.[57,66] Stewardship and potential contribution to antibiotic resistance and environmental impact warrant further study.

Mixed or Multihazardous Wastes

The most stringent regulation should be used for handling and disposal when healthcare wastes are mixed; these may include infectious wastes that also contain hazardous chemicals or radionuclides.[1,13,19]

'22'30'67

Chemotherapeutics

Handling and disposal of antineoplastic and cytotoxic drugs used for chemotherapy present potential risks for patients and workers. The drugs and related supplies should be addressed in the waste management plan.[7,57] Per the National Institute for Occupational Safety and Health, workers at risk of exposure to these hazardous drugs include "shipping and receiving personnel; pharmacists and pharmacy technicians; nursing personnel; physicians; operating room personnel; environmental services personnel; and personnel involved in veterinary practices where hazardous drugs are used."[68] Because these drugs are filtered and may be concentrated by the kidneys, urine from treated patients should be handled and discarded with care.[57,68]

Radioactive Materials

Facilities using radiopharmaceutical therapy must have specific procedures in place for the handling and disposal of radioactive wastes that may also contain bloodborne pathogens (i.e., those mixed with blood, body fluids, or tissues).[67] Although radioactive patient excreta released into the sanitary sewer is typically exempted from most regulatory requirements, the collection of the same radioactive excreta into a diaper requires that this previously not-included and unregulated waste must now be managed as radioactive waste. It is important to remain cognizant of other instances when potentially infectious materials contaminated with radioactive materials can become a waste management concern for the organization. Examples include the following:

- A patient with recent dosing experienced gastrointestinal bleeding and required emergency surgery with follow-up care in the intensive care unit. Staff may be exposed to blood and tissue that is radioactive (e.g., I-sodium iodide dose for thyroid ablation) and contains potential bloodborne pathogens.[69,70] Subsequent pathology and postmortem care may also require special handling of tissues and wastes.[69]
- Brachytherapy for the treatment of prostate cancer includes implantation of radioactive seeds into the prostate. Infection prevention and waste handling for the procedure area and subsequent follow-up with the patient in the clinic or at home must be considered if this treatment is provided.[71]
- Technetium 99-m labeling is used to identify sentinel nodes for surgical excision in cancer, such as for patients with melanoma or breast cancer. Specific procedures must be developed for this radioactive material in the surgical area and laboratory where excised tissue may be processed and discarded.[72]

Most hospitals have a radiation safety officer (RSO) or health physicist that is responsible for ensuring the safe use of radioactive materials. The RSO is an invaluable resource for the IP faced with a radioactive waste management concern and can provide guidance on effective means to manage potentially infectious waste contaminated with radioactive materials.

Emerging Infectious Agents and Potential Bioterrorism Agents

Selected agents, including microbes and biologicals, have been identified based on their risk to national security or public health, and each facility must have the capacity to destroy discarded cultures and

stocks on-site.[6,21] The emergence of new infectious agents may present new challenges in waste disposal, especially when knowledge about a causative agent is limited and information about transmission or infectious nature is incomplete, such as was seen with severe acute respiratory syndrome coronavirus in the early 2000s. In these cases, stringent recommendations for waste handling and disposal are often implemented.[6,73] Tissues and certain wastes from prion diseases such as Creutzfeldt-Jakob disease and the variant strain causing bovine spongiform encephalopathy, commonly called mad cow disease, require special handling and disposal.[6] (Also see **96. Viral Hemorrhagic Fevers**, and **73 Creutzfeldt-Jakob Disease and Other Prion Diseases**.) Incineration with a minimum secondary temperature of 1,000°C or alkaline hydrolysis using pressurized 1 N NaOH or KOH at 150°C are two possible disposal methods for animal carcasses and other tissues suspected of containing prions.[21]

Potential bioterrorism agents, such as smallpox, have prompted guidance that includes waste handling and disposal.[74,75] For example, in smallpox vaccination plans, the handling and disposal of bifurcated needles, vaccination site dressings, and discarded unused vaccine must be addressed for safe waste management.[74] (Also see **120. Infectious Disease Disasters: Bioterrorism, Emerging Infections, and Pandemics**.)

New Technologies for Waste Treatment

Many technologies are available or under development to treat or decontaminate regulated medical wastes. Methods reduce microbial load, and the final waste product does not need to be sterile prior to disposal.[6,13,20] Processes include autoclaving, incineration, internment (anatomic wastes), chemical disinfection, grinding/shredding/disinfection methods, energy-based technology (microwave or radio waves), disinfection/encapsulation, and disposal into a sanitary sewer.[6,35] Incineration is an effective method for treating most medical wastes and is appropriate for antineoplastics; however, it should not be used for radionuclides.[13,15,64,65] Regulation at federal and state levels, due to environmental impact, has limited the availability of incinerators, so alternative methodologies—both on-site and off-site—are being utilized.[13,30,33,35,76,77] Criteria for choosing treatment include suitability for types of waste, risks related to handling, effectiveness of treatment, uniformity or quality of process, costs (capital, operating, startup, labor, materials), success of process (experience of others using same method), occupational and environmental risks, reduction in waste volume and weight, community acceptance, and applicable regulatory compliance.[13]

Performance Improvement

To help assess the effectiveness of the waste management plan, performance improvement measurements can be used. For instance, The Joint Commission standards may be referenced when identifying and documenting a performance improvement activity.[9] Examples of performance improvement related to waste include (1) monitoring exposures to body fluids and sharps injuries related to disposals of contaminated needles; (2) monitoring of the "fullness" of needle boxes to indicate if the boxes are changed at proper intervals; and (3) evaluation of sorting waste appropriately with a visual audit or evaluation of contents in waste containers (appropriate precautions are required if the latter approach is used). Periodic audits of waste generation areas and accumulation points, including questioning of staff on appropriate waste management procedures, can help an organization identify opportunities for training and process improvements. Regardless of the performance improvement monitors selected, the

data should be used to ensure the program is working. Data analysis and reports of performance improvement measures provide objective measures to verify the effectiveness of any corrective actions taken and identify opportunities for improvement. Cost-reduction strategies may follow the same strategy as outlined in a report by Garcia describing interventions and related improvement measurements to reduce the volume of waste.[78]

Conclusions

This chapter provides a brief historical overview and the practical information necessary for the appropriate management of wastes generated in healthcare settings that may present an infectious risk. "The most practical approach to medical waste management is to identify waste that represent[s] a sufficient potential risk of causing infection during handling and disposal and for which some precautions likely are prudent."[5]Additional information related to waste management is provided to assist the IP with other types of waste that may be found in today's varied healthcare settings.

Future Trends

Costs for packaging, segregation, treatment, and disposal of infectious waste will likely increase in the future. Incineration will likely continue to decline as other treatment technologies develop and regulations on incinerators become more stringent. Scientific-based studies to characterize the risks associated with healthcare wastes will assist lawmakers in updating regulations. Recycling of some items currently categorized as infectious waste is under consideration, with estimates that between 30 to 50 percent of medical waste can be recycled. As stated by Daschner, "There are no infectious risks associated with recycling hospital waste."[79]Environmental stewardship will also prompt continued interest in interventions to minimize waste volume, such as reusable disposal containers. As resources become more limited and environmental concerns intensify, innovative approaches to managing healthcare wastes will continue to evolve.

International Perspective

A review of the permutations and combinations of waste management systems in use throughout the international community is beyond the scope of this chapter. However, the literature suggests that waste management systems vary drastically from none at all to highly regulated functioning systems.[25,79,80,81,82,83,84]Many countries have considered the regulations and guidelines promulgated in the United States to help establish their own standards. Some countries have encountered "growing pains" similar to those the U.S. healthcare community went through in the 1980s and 1990s.

For example, in Great Britain, according to one author, digging a hole, burying medical waste, and then covering successive layers with lime is a common practice when items cannot be incinerated.[80]Problems associated with infectious waste disposal practices are compounded in undeveloped countries where trash may be dumped anywhere. Trash "pickers" commonly rummage through discarded trash to find usable or salable items.[81]Children are often involved, and this practice represents another source of infectious disease exposure beyond those caused by poor sanitation, lack of safe food and water, and

poor medical care. Unfortunately, in some instances, the mismanagement of healthcare waste has caused some institutions in developing countries to give up single-use syringes in favor of reusable glass syringes. While this eliminates the waste management issues, it is causing the return of infections due to the use of unsterilized syringes.[4]The following are a few examples of general infectious waste issues that have been cited in the international literature:

- Absence of professional training in how to handle these wastes[81]
- So many other medical concerns that waste management, in general, is ignored[81]
- Licensing standards are unclear, conflicting, or confusing[31,82]
- Inadequate incineration/sterilization[82]
- No plans in place for collection and storage[82]
- Some have laws/regulations, but they are not enforced[82]
- Needles and syringes are commonly thrown in the regular trash[83]
- Lack of finances/resources prohibits implementation[84]
- No availability of technologies[84]

Those in the international community looking to implement a practical, scientific, infectious waste management program can refer to the body of this chapter in addition to references cited and the supplemental resources provided.

Abstract

This chapter addresses the role of infection prevention and control in the environment with a specific focus on heating, ventilation, and air conditioning systems in healthcare facilities. Maintaining both comfort and safety of indoor air quality in healthcare facilities is essential for all occupants. Specifically, poor design and installation, system performance problems, and inadequate maintenance of heating, ventilation, and air conditioning systems have all been associated with transmission of airborne infectious agents and/or building-associated illness. Environmental containment/mitigation of airborne infectious agents (e.g., Mycobacterium tuberculosis, Aspergillus *spp., varicella zoster and measles viruses, plus newly emergent pathogens such as severe acute respiratory syndrome-associated coronavirus) and preparedness for deliberate use of pathogens as bioweapons are vital areas the infection preventionist can provide expertise for their affiliated facility.*

Key Concepts

• Understanding the terminology and knowing how to assess and evaluate heating, ventilation, and air conditioning systems has become part of the infection preventionist's set of skills needed to prevent and control transmission of airborne infectious agents.

• This chapter should be reviewed in conjunction with **115. Water Systems Issues and Prevention of Waterborne Infectious Diseases in Healthcare Facilities**, and , because many of these systems are

interrelated. This chapter considers examples of ventilation-associated health hazards, regulatory agencies impacting or setting standards for ventilation specifications, and environmental monitoring.

• Details of ventilation requirements for specialty areas of healthcare facilities are included to assist with planning and design activities.

Background

BASIC FEATURES OF A HEATING, VENTILATION, AND AIR CONDITIONING SYSTEM

The impact of ventilation on health in any setting is far-reaching and is an essential component of the infection control risk assessment (ICRA) and associated risk mitigation interventions described in . Therefore, a basic understanding of key terms, concepts, and effects on the health of patients and healthcare personnel (HCP) is essential to providing appropriate input into the ICRA and assuring the heating, ventilation, and air conditioning (HVAC) system is providing as safe and comfortable an environment as possible.

HVAC describes a facility's overall air handling system: heating, ventilation, and air conditioning. Indoor air ventilation or HVAC systems supply, filter, condition (heat, cool, humidify, dehumidify), and exhaust air by a variety of design schemes. A core component of a centralized HVAC system is an air handling unit (AHU), which most often is located on a roof or in a mechanical room. Decentralized approaches in separate rooms often utilize individual fan coil units that are usually installed under windows, draw air through grills on outside walls, and mix outside air with recirculated air within the room. Both systems have infection prevention and control implications for indoor air quality (IAQ) and infection prevention and control issues related to ventilation problems. Typical components of an HVAC system are illustrated in Figure 114-1.

Additional discussion of HVAC system design are available in other resources.[1,2,3]Numerous studies identifying problems such as clusters or increased rates of building-associated infections attributed to HVAC systems have been described and are reviewed in this chapter.[4,5,6,7,8,9,10,11]

Basic Principles

CROSS-TRANSMISSION OF AIRBORNE INFECTIONS IN HEALTHCARE FACILITIES INVOLVING HEATING, VENTILATION, AND AIR CONDITIONING

Although infrequent, HVAC systems can be a source of exposure and infection caused by airborne infectious agents. Specifically, airborne opportunistic pathogens or saprophytes from other reservoirs may present a hazard in general patient areas, the operating room (OR), central decontamination and sterilization centers, and diagnostic procedure rooms as well as in kitchens and general waiting rooms.[1,2,3,4,5,6,7,8,9,10,11,12,13,14]*Aspergillus*, *Rhizopus*, and *Penicillium*species, as well as fungi from other sources, may be hazardous to immunosuppressed patients.[15]Moisture-associated fungi such as *Acremonium kiliense*may contaminate an air handler and spread to patients through ventilation systems.[1'4'11'16'17]*Legionella*spp. from nearby environmental water sources may enter hospital water systems,

multiply in cooling towers and evaporative condensers, and contaminate the potable water system.[1,4] The following examples of reported clusters of infections caused by various microorganisms illustrate the role HVAC systems have played in each:

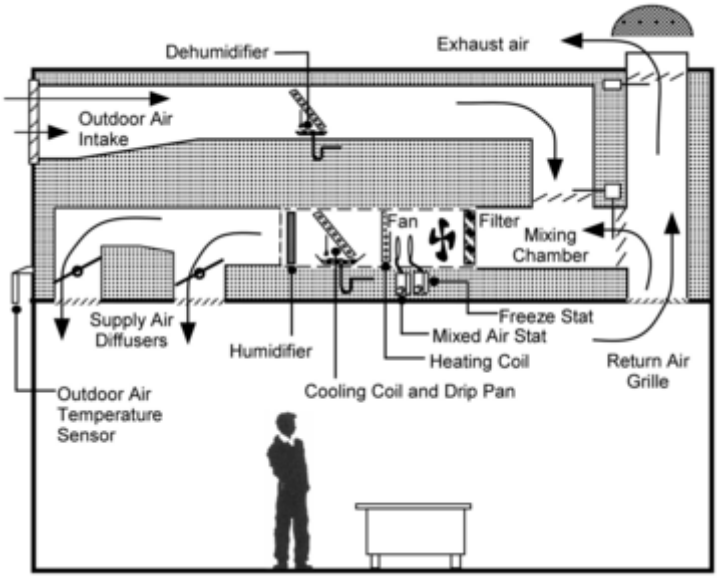

Figure 114-1.

Typical HVAC system components. (From Centers for Disease Control and Prevention (CDC). Building air quality: A guide for building owners and facility managers. Appendix B: HVAC Systems and Indoor Air Quality, 1991. EPA Publication No. 400/1-91/003. CDC website. 2013. Available at: **http://www.cdc.gov/niosh/baqt** View Image

• Neonatal intensive care unit (NICU) ventilation: *Rhizopus* and *Aspergillus* species were implicated in premature infants with pulmonary abscesses identified at autopsy. The outbreak was associated with fungi recovered from environmental sampling in the NICU near a construction area. Ventilation, dust above false ceilings, and ineffective barriers were all associated with the outbreak.[18]

• Cardiac surgery: An outbreak of *Aspergillus* endocarditis following open-heart surgery implicated the OR ventilation system. Investigation found the aspergilli to be ubiquitous. Critical issues included location of air intake, filtration efficiency, and number of air changes. Improving the ventilation standards to those recommended at the time appeared to prevent any new cases.[19]

• Hematology unit: An outbreak of *Aspergillus* infection among patients with leukemia or bone marrow transplantation was found to be associated with various construction-associated factors including ventilation. Interventions that appeared to control the outbreak included sealing of windows, installing nonperforated ceiling tiles, use of high-efficiency particulate air (HEPA) filter air purifiers, and other dust-reducing methods.[20]

• Surgical suite: *Cladosporium* and *Penicillium* spp. were associated with major problems in surgical suite ventilation, showing the importance of designing and maintaining HVAC systems. Important issues included the role of contaminated duct linings, need for filter replacement, and sealed windows.[13]

• Hospital: Healthcare-associated transmission of multidrug-resistant *M. tuberculosis* involved at least 13 patients in a New York hospital. Before full implementation of Centers for Disease Control and Prevention (CDC) guidelines, only 1 of 16 isolation rooms tested was under negative pressure. Many factors were identified and addressed, but installation of proper air-handling equipment and related monitoring were identified as major contributing factors in ending the outbreak.[21]

Table 114-1 Illustrative Studies on Impact of Microbial Contamination of Air Handling Systems and Interventions

Airborne Contaminants

Year—Author (Reference)	Organism	Population	Epidemiological Factors	Remedial or Preventive Measures
1986 Opal et al.[22]	*Aspergillus*spp.	BMT	Construction activity	Sealed barriers; HEPA filter; antifungal
1987 Streifel et al.[12]	*Penicillium*spp.	BMT	Moisture; rotted wood cabinet; fungal release	Replace with nonporous surfaces around sink
1987 Weems et al.[11]	*Rhizopus; Mucor*spp.	Hematological BMT	Construction activity, dust, traffic, HVAC	Construction plans: HVAC; sealed barriers to window infiltration
1990 Fox et al.[13]	*Penicillium*spp.; *Cladosporium*spp.	OR	Ventilation duct lined; contaminated fiberglass insulation	Decontamination of HVAC ductwork; filter replacement
1992 Hruszkewycz et al.[7]	*Penicillium*spp. *Aspergillus*spp.	Laboratory pseudo-outbreak	Improper airflow during renovation near lab; false ceiling in work area	Sealed ceilings; proper use of hoods and appropriate airflow controls
1994 Iwen et al.[23]	*Aspergillus*spp. Mixed fungi	BMT Unit	Improper airflow; suspected infiltration from windows	Sealed windows and balanced airflow; replaced HEPA filters
1996 Anderson et al.[24]	*Aspergillus*spp.	Pediatric oncology unit	Improper airflow from clinical waste disposal room	Sealing disposal room; HEPA filtered vacuum cleaners
1994 Pittet et al.[25]	*Aspergillus*spp.	COPD	Air filter replacement	Replace and monitor filter function
1998 Kumari et al.[26]	*Methicillin*-resistant *S. aureus*	Orthopedic patients	Ventilation grills	Cleaned, maintained pressure relationships
1997 Dearborn et al.[27]	*Stachybotrys atra*	Infants	Water damaged homes; suspected airborne toxin	Rapid/vigorous cleaning/decontaminate with diluted bleach
1996 Fridkin et al.[17]	*Acremonium kiliensis*	Ambulatory surgery–system	Poorly designed HVAC; contaminated humidifier	Redesign; changed HEPA filters; proper HVAC maintenance
2002 Anaissie et al.[28]	*Aspergillus*spp.	BMT	Concentration of airborne fungi on shower surfaces	Clean shower floor with detergent prior to use of shower

Several outbreaks representing the role of various organism and epidemiologic methods to resolve them are described in Table 114-1.[7,11,12,13,17,22,23,24,25,26,27,28] It is worth noting that association of disease with recovery of *Stachybotrys* from the environment has been re-examined in a recent review that identified flaws in the epidemiologic analysis of earlier studies of hemosiderosis in infants.[27,29] As a result, experts have not found well-substantiated supportive evidence of serious illness owing to *Stachybotrys atra* exposure in the contemporary environment. These earlier investigations now appear misleading; however, that has not deterred medicolegal claims from making it the 21st century "asbestos" problem.

Ventilation Standards, Design, Interventions and Outcomes

REGULATIONS AND STANDARDS

Regulatory and accrediting agencies base licensing and/or certification decisions on whether facilities meet minimum construction standards. Agencies and professional groups concerned with HVAC design are similar to those involved with construction.

The broadest source of authority affecting ventilation design and implementation is the *2006 Guidelines for Design and Construction of Health Care Facilities*. This consensus document is written and published by the Facility Guidelines Institute (FGI) and the American Institute of Architects (AIA) Academy of Architecture for Health/Facility Guidelines Institute with assistance from the U.S. Department of Health and Human Services (HHS).[30]The content of this consensus document is updated every 3 to 4 years by the FGI. Beginning with the 2010 edition, the Guidelines will be published by the American Society for Healthcare Engineering (ASHE) and FGI with assistance from HHS and should be referenced as the FGI Guidelines. In this chapter they will be referred to as the FGI/AIA Guidelines. Most states in the United States adopt these Guidelines in their entirety or with some modifications as minimum standards for design and construction of healthcare facilities in their respective states. The FGI/AIA guidelines rely heavily on input from many professional and guideline-setting organizations such The Joint Commission (TJC).[31]

Other guidelines, recommendations, and standards related to HVAC systems include:

• American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE): (1) Ventilation and filtration tables[32,33]; (2) ANSI/ASHRAE/ASHE Standard 170, Ventilation of Health Care Facilities, is a new standard that closely mirrors parameters in 2006 FGI Guidelines. FGI and ASHRAE are collaborating closely to adopt a single, unified table that describes design parameters for HVAC systems.[33]

• The CDC and its federal research agency, the National Institute for Occupational Safety and Health (NIOSH): ventilation requirements for negative air-pressure rooms, design and ventilation recommendations for positive air-pressure rooms, construction and renovation recommendations, and design of HVAC to mitigate risks from airborne chemical, biological, or radiological attacks.[1,4,5,34,35]

• National Fire Protection Association (NFPA): selected NFPA codes and standards are critical elements incorporated into the FGI/AIA Guidelines and enforced by all accreditors and regulators.[30]

• The Centers for Medicare & Medicaid Services (CMS) Conditions of Participation for Medicare and Medicaid (CoP): whereas the "physical environment" and ventilation standards include the NFPA codes, they are broadly stated. Interpretations are usually based on federal and state construction codes developed from the FGI/AIA Guidelines as noted.[36]

• State authorities having jurisdiction (AHJs): provide necessary assistance in the interpretation of federal and/or FGI/AIA Guidelines with individual state requirements. State health departments managing the plan and review function are important to the consensus review process.[3,37]

• Occupational Safety and Health Administration (OSHA): enforces aspects of air quality that may present hazards to HCP such as tuberculosis (TB) and legionellosis but also other contaminants present in the air in hospitals to include waste anesthetic gases and vapors from select chemicals.[38]Although OSHA withdrew its proposed TB standard in May 2003, it enforces aspects of air quality that may present hazards to employees, such as TB, under the auspices of the "general duty clause" using

related compliance documents, or specific standards, as applicable. State regulations must be equally as effective as those required by OSHA.[39,40,41]

• Environmental Protection Agency (EPA): has standards related to medical waste and air contamination (e.g., incinerators and emissions) that are considered for air-intake design and placement (see Supplemental Resources). The EPA also has published or sponsored several resources related to indoor air quality and control/response to instances of mold contamination in buildings.[42]

• Voluntary accreditation agencies: for example, TJC, American Osteopathic Association (AOA), and the National Committee for Quality Assurance (NCQA).

As noted, FGI/AIA Guidelines have been adopted by TJC in its environment of care (EOC) standards, but as of 2009, TJC continues to reference the 2001 edition specifically in the Statement of Conditions that are prepared by each facility. TJC updated the EOC standards with explicit requirements for utility management that have a direct relationship with the FGI/AIA Guidelines and explicitly reference infection prevention and control issues in the intent of the EOC standards. In 2002, TJC added a requirement for performing an ICRA. They also modified the EOC standards in all accreditation manuals. TJC has stated its intent to enforce their standards in light of the 2010 Guidelines after publication in early 2010. Other agencies and managed care organizations may develop their own physical facility standards for outpatient clinics and other care sites based on CMS/CoP or indirectly on the Guidelines.[1,4,5,30,31,36](See **4. Accrediting and Regulatory Agencies**.)

HEATING, VENTILATION, AND AIR CONDITIONING BASIC DESIGN AND TERMINOLOGY

Some HVAC systems are designed to supply 100 percent outdoor (fresh) air, whereas others mix a percentage of the exhaust air (subject to code allowances) with supply air from the outdoors to save on operational costs. The air is conditioned by passing through filters and is heated/cooled, and humidified/dehumidified through the HVAC apparatus before distribution.[30,43]

Air Source

Outdoor Air

The major reason for pulling fresh, outdoor air is dilution of microbial contamination, gases, and odor control.

Recirculated Air

Given current use of nonflammable anesthesia gases, even ORs may conserve energy and use a portion of recirculated air. If any form of variable air volume (VAV) is used for energy conservation, it must not compromise the corridor-to-room pressure balancing relationships or the minimum air changes described in the 2006 Guidelines.[30](See Table 2.1-2 of the 2006 Guidelines for specific restrictions.)

Tables 114-2 and 114-3 are based on the 2006 Guidelines, Tables 2.1-2 and 2.1-3, and summarize the design specifications related to air changes and filtration. It should be noted that Table 2.1-2 describes specifications only for hospitals and ambulatory care. Chapter 3 of the 2006 Guidelines contains a similar table that is applicable to nursing homes and other long-term care facilities. Importantly, the HVAC parameters in the 2006 Guidelines, reproduced in this chapter, specify design—not operational—parameters for this utility system. The rationale is that given the wide variation in climate for various

geographic regions in the United States, it would be impractical to require continuous, ongoing monitoring of air exchange, temperature, and humidity for all facilities. These latter aspects are operational—meaning, the facility-based personnel determine how often and with what mechanism these need to be monitored.

Air Changes

Air changes per hour (ACH), or the ventilation rate, are the number of times the air volume of a given space is replaced in a 1-hour period and includes sufficient changes of outside air to dilute microbial contamination and gases. Studies have shown that a minimum of two ACH of outside air is all that is needed to remove odors. However, recent work has shown that for comfort the total number in patient rooms should be six ACH. As noted in the appendix to Table 114-2 and , this can be modified under certain conditions.[30,44,45] There are no standards or guidelines governing the frequency of ACH measurements for specialty areas (e.g., surgical suite or airborne infection isolation [AII] rooms). An organization should determine its own inspection and maintenance schedule based on facility-specific data. Some facilities set up semiannual testing for specialty areas; others schedule tests to ensure the entire facility is checked over a 5-year span. At a minimum, state licensure inspectors and/or TJC surveyors do expect to see a documented plan.

Table 114-2.Ventilation Requirements for Areas Affecting Patient Care in Hospitals and Outpatient Facilities[1]*

Table 114-2 Ventilation Requirements for Areas Affecting Patient Care in Hospitals and Outpatient Facilities

Area Designation	Air Movement Relationship to Adjacent Area[2]	Minimum Air Changes (AC) of Outdoor Air/hr[3]	Minimum Total AC/hr[4,5]	All Air Exhausted Directly to Outdoors[6]	Recirculation by Means of Room Units[7]	Relative Humidity[8]

1The ventilation rates in this table cover ventilation for comfort, as well as for asepsis and odor control in areas of acute care hospitals that directly affect patient care and are determined based on healthcare facilities being predominantly "no smoking" facilities. Where smoking may be allowed, ventilation will need adjustment. Areas where specific ventilation rates are not given in the table shall be ventilated in accordance with ASHRAE Standard 62 Ventilation for Acceptable Indoor Air Quality, and ASHRAE: Handbook of Applications. Specialized patient care areas, including organ transplant units, burn units, specialty procedure rooms, etc., shall have additional ventilation provisions for air quality control as may be appropriate. Occupational Safety and Health Administration (OSHA) standards and/or National Institute for Occupational Safety and Health (NIOSH) criteria require special ventilation requirements for employee health and safety within healthcare facilities.

2Design of the ventilation system shall provide air movement, which is generally from clean to less clean areas. If any form of variable air volume or load shedding system is used for energy conservation, it must not compromise the corridor-to-room pressure balancing relationships or the minimum air changes required by the table.

3To satisfy exhaust needs, replacement air from outside is necessary. Table 2.1-230 does not attempt to describe specific amounts of outside air to be supplied to individual spaces, except for certain areas as those listed. Distribution of outside air, added to the system to balance required exhaust, shall be as required by good engineering practice. Minimum outside air quantities shall remain constant while the system is in operation. In variable volume systems, the minimum outside air setting on the air-handling unit shall be calculated using the ASHRAE 62 method.

4Number of air changes may be reduced when the room is unoccupied if provisions are made to ensure that the number of air

changes indicated is reestablished any time the space is being utilized. Adjustments shall include provisions to ensure that the direction of air movement remains the same when the number of air changes is reduced. Areas not indicated as having continuous directional control may have ventilation systems shut down when space is unoccupied and ventilation is not otherwise needed, if the maximum infiltration or exfiltration permitted in Note 2 is not exceeded and if adjacent pressure balancing relationships are not compromised. Air quantity calculations must account for filter loading such that the indicated air change rates are provided up until the time of filter change-out. The minimum total air change requirements for the Ventilation Table shall be based on the supply air quantity in positive pressure rooms, and the exhaust air quantity in negative pressure rooms.

5Air change requirements indicated are minimum values. Higher values should be used when required to maintain indicated room conditions (temperature and humidity) based on the cooling load of the space (lights, equipment, people, exterior walls and windows, etc.).

6Air from areas with contamination and/or odor problems shall be exhausted to the outside and not recirculated to other areas. Note that individual circumstances may require special consideration for air exhaust to the outside, such as in intensive care units in which patients with pulmonary infection are treated, or rooms for burn patients.

7Recirculating room HVAC units refer to those local units that are used primarily for heating and cooling of air, and not disinfection of air. Because of cleaning difficulty and potential for buildup of contamination, recirculating room units shall not be used in areas marked "No." However, for airborne infection control, air may be recirculated within individual isolation rooms if HEPA filters are used. Isolation and intensive care rooms may be ventilated by reheat induction units in which only the primary air supplied from a central system passes through the reheat unit. Gravity-type heating or cooling units, such as radiators and convectors, shall not be used in

operating rooms and other special-care areas. (See Footnote Appendix A7 for a description of recirculation units to be used in isolation rooms.)

8The ranges listed are minimum and maximum limits where control is specifically needed. The maximum and minimum limits are not intended to be independent of a spaces' associated temperature. The humidity is expected to be at the higher end of the range when the temperature is also at the higher end and vice versa. See Figure 2.1-130 for a graphic representation of the indicated changes on a psychrometric chart. Shaded area is acceptable range.

9Where temperature ranges are indicated, the systems shall be capable of maintaining the rooms at any point within the range during normal operation. A single figure indicates a heating or cooling capacity of at least the indicated temperature. This is usually applicable when patients may be undressed and require a warmer environment. Nothing in these guidelines shall be construed as precluding the use of temperature lower than those noted when patients' comfort and medical conditions make lower temperatures desirable. Unoccupied areas, such as storage rooms, shall have temperature appropriate for the function intended.

10Total air changes per room for patient rooms, intermediate care, labor/delivery/recovery rooms, and labor/delivery/recovery/postpartum rooms may be reduced to four when supplemental heating and/or cooling systems (radiant heating and cooling, baseboard heating, etc.) are used.

11Differential pressure shall be a minimum of 0.01-in. water gauge (2.5 Pa). If alarms are installed, allowances shall be made to prevent nuisance alarms of monitoring devices.

12If it is not practical to exhaust the air from airborne infection isolation rooms to the outside, the air may be returned through HEPA filters to the air-handling system exclusively serving the isolation room.

13National Institute for Occupational Safety and Health

(NIOSH) criteria documents regarding Occupational Exposure to Waste Anesthetic Gases and Vapors, and Control of Occupational Exposure to Nitrous Oxide, indicate a need for both local exhaust (scavenging) systems and general ventilation of the areas in which the respective gases are utilized.

14Some surgeons may require room temperatures that are outside of the indicated range. All operating room design conditions shall be developed in consultation with surgeons, anesthesiologists, and nursing staff.

15The term trauma room as used here is the operating room space in the emergency department or other trauma reception area that is used for emergency surgery. The first aid room and/or "emergency room" used for initial treatment of accident victims may be ventilated as noted for the "treatment room." Treatment rooms used for bronchoscopy shall be treated as bronchoscopy rooms. Treatment rooms used for cryosurgery procedures with nitrous oxide shall contain provisions for exhausting waste gases.

16In a ventilation system that recirculates air, HEPA filters can be used in lieu of exhausting the air from these spaces to the outside. In this application, the return air shall be passed through the HEPA filters before it is introduced into any other spaces.

17The endoscopic instrument processing room is a room adjacent to the gastrointestinal endoscopy room that is utilized for cleaning of endoscopic equipment and instruments.

18When required, appropriate hoods and exhaust devices for the removal of noxious gases or chemical vapors shall be provided (see NFPA 99).

19The air movement relationships for laboratories apply between laboratory and adjacent nonlaboratory spaces. Reference DHHS publication Biosafety in Microbiological and Biomedical Laboratories (CDC and NIH) on the CDC website. Appendix footnotes for Footnotes 7 and 11 provide additional nonbinding guidance.

[A7]Recirculating devices with HEPA filters may have potential uses in

existing facilities as interim, supplemental environmental controls to meet requirements for the control of airborne infectious agents. Limitations in design must be recognized. The design of either portable or fixed systems should prevent stagnation and short circuiting of airflow. The supply and exhaust locations should direct clean air to areas where healthcare personnel are likely to work, across the infectious source, and then to the exhaust, so that healthcare personnel are not in position between the infectious source and the exhaust location. The design of such systems should also allow for easy access for scheduled preventative maintenance and cleaning.

[A11]The verification of airflow direction can include a simple visual method such as smoke trail, ball-in-tube, or flutter strip. These devices will require a minimum differential air pressure to indicate airflow direction.

Adapted from American Institute of Architects/Academy of Architecture for Health, Facility Guidelines Institute. *2006 Guidelines for Design and Construction of Healthcare Facilities*. Washington, DC: The American Institute of Architects Press, 2006.

Air Pressurization and Balancing

General

Air pressure balancing describes the pressure relationships with respect to the surrounding area or corridor and can be positive (excess air supply in the room), negative (air drawn into the room), or neutral. Positive air pressure is used to keep microbial contamination out of the room and is used for immunosuppressed patients such as those undergoing bone marrow transplantation. Positive air pressure is used in ORs, special procedure rooms, and protective environment (PE), for example. Negative air pressure is used as an isolation measure to keep microbes from escaping from the room and is used for patients infected with organisms transmitted by the airborne route, such as TB, measles, and varicella. Other examples of areas requiring negative pressure include rooms such as toilet rooms, bronchoscopy room, triage, and emergency department waiting rooms.[30](See Table 114-2 for all areas requiring positive or negative air pressure.)

Table 114-3 Filter Efficiencies for Central Ventilation and Air Conditioning Systems in General Hospitals

	Filter Efficiencies (percent)

Area Designation	Number of Filter Beds	Filter Bed No. 1 (MERV, %)	Filter Bed No. 2 (MERV, %)
All areas for inpatient care, treatment, and diagnosis, and those areas providing direct service or clean supplies such as sterile and clean processing, etc.	2	8 (30)	14 (90)
Protective environment	2	8 (30)	HEPA (99.97)
Laboratories	1	13 (80)	—
Administrative, bulk storage, soiled holding areas, food preparation, and laundries	1	8 (30)	—

Additional roughing or prefilters should be considered to reduce maintenance required for filters with efficiencies higher than 75 percent.

MERV, minimum efficiency rating value. MERVs are based on ASHRAE 52.2. The filtration efficiency ratings are based on average dust spot efficiency per ASHRAE 52.1-92.

American Institute of Architects/Academy of Architecture for Health, Facility Guidelines Institute. *2006 Guidelines for Design and Construction of Healthcare Facilities*. Washington, DC: The American Institute of Architects Press, 2006.

Air Pressure Testing

Air pressure testing includes use of built-in pressure manometers, qualitative tests (e.g., smoke trails, electronic meters), and quantitative methods.[46] Table 114-2 (Table 2.1-2 in the 2006 Guidelines)[30] specifies that the differential pressure should be a minimum of 0.01-inch water gauge or 2.5 Pascals (Pa) for operating, bronchoscopy, and AII rooms and PEs. This quantitative measure evaluates the adequacy of the air movement relationships to adjacent areas. This is not the only important parameter, however. A published study found that detection of a pressure difference between the inside and outside of a room did not necessarily correlate with the direction of airflow.[47] It was deemed critical to employ devices that provide visual demonstration of the direction of airflow (e.g., smoke trails, flutter strips, ball-in-a-tube) in addition to continuous or built-in air monitors. The 2006 Guidelines mandate that major renovation or new construction of specialty rooms must include a "permanently installed visual means" to measure airflow direction.[30]

OSHA directives require facilities follow CDC TB Guidelines,[5,41] which specify daily verification and documentation that AII rooms remain in negative pressure with respect to the adjacent corridor when in use for care of patients with suspect or known pulmonary or laryngeal TB.[38,39] Thereafter, the CDC recommends monthly checks of AII rooms when not in use, even if electronic alarm pressurization monitors are installed.

Variations in airflow make maintaining pressure differentials difficult; the 2006 Guidelines therefore continue to strongly recommend against "reversible" room airflow.[30] The basis for this position is that point-of-use monitors may not be reliable, leakage of air from rooms is common, and personnel may not be aware if the room is in positive or negative pressurization.[48]

Filtration

HVAC systems use prefilters before fans to remove gross particulate matter (minimum efficiency 30 percent). Filters that are 85 to 90 percent efficient are placed downstream of the fans after the prefilters. This combination typically provides an overall filtration of 95 percent efficiency. HEPA filtration is defined as filtration with efficiency of 99.97 percent in removing particles 0.3 micron or more in size. Most airborne infectious microorganisms fall into a range of 0.3 to 5.0 microns. Filters that are 90 percent efficient as measured by industry standards remove sufficient particulate matter to meet minimum OR standards.[30,32,49]ASHRAE introduced a system for rating filters that is based on the size of particle or contaminant to be filtered. This measure of "minimum efficiency reporting values" (MERV) uses a scale of 1 through 16. In this system, a 30 percent efficient filter equates to MERV 8; 80 percent is equivalent to MERV 13; 90 to 95 percent equates to MERV 14; and 95 percent equals MERV 15.[33,34,35]Both systems can be used interchangeably. Removal and disposal of used filters requires basic care (careful handling/bagging); however, filter media, even from AII rooms, is not classified as regulated medical waste and may be disposed into the general waste stream. Studies have demonstrated the nonviability of microorganisms in used filters, such as *M. tuberculosis*.[50]

Distribution and Diffusion of Air

Airflow supply and exhaust should be controlled to ensure movement of air from "clean" to "less clean" areas, especially in critical areas. Cleaned, filtered air (supply) is typically distributed by directing airflow into the room from ceiling outlets near the center of the work area and moving to the periphery. Return air (exhaust) should be near floor level, although designs may vary. Once air enters the room, it is affected by other sources of contamination introduced by equipment and people (staff and patients) entering and leaving. Effective exhaust and removal of contaminants are basic to maintaining excellent air quality.

Laminar airflow (LAF) refers to a directional flow of air with little to no turbulence. It can be directed vertically or horizontally, and, when in place, recirculated air is usually passed through a HEPA filter. LAF is used to supply a steady stream of clean air across or down a room and is used primarily in specialty type ORs (e.g., orthopedic surgery). It is designed to move particle-free air ("ultraclean air") over the aseptic operating field at a uniform speed, removing particles from its path. The CDC *1999 Surgical Site Infection Prevention Guideline*recommended, "consider performing orthopedic implant operations in operating rooms supplied with ultraclean air," which indirectly implies a combination of LAF plus HEPA filter media.[51]Subsequent CDC Guidelines, assessing available scientific literature, reclassified this to state, "No recommendation is offered for performing orthopedic implant operations in rooms supplied with laminar airflow."[1]

Recent studies using computational fluid dynamics (CFD)-assisted modeling have examined which design optimizes removal of airborne particulates over the surgical site to attempt to resolve conflicting findings in the literature. Memarzadeh and Manning incorporated ACH, velocity, and unidirectional airflow into their CFD study with several variations in placement of personnel, equipment, and return (exhaust) air, and measured particle contamination of the surgical field. They found that ACH higher than 25 are not any more effective but that velocity and directional airflow do have greater influence on particle removal.[52,53]In addition, use of low velocity (25–35 feet/minute [fpm]) rather than traditional high velocity LAF (90–400 fpm) was also found more effective. Another key finding was that there is a thermal plume or "heat bounce" up from the incision on the patient's skin that moves particles up and away from the incision. High velocity LAF is likely negating this natural protection of the site and may be cooling the

wound bed and the patient. Hypothermia contributes to risk of both infectious and noninfectious postoperative complications. FGI/AIA and ASHRAE agreed that the desired "directional" ventilation should be termed "noninduction unidirectional diffusion" to avoid the confusion with the term LAF. This term describes a unidirectional flow of air downward over the patient and the surgical team at a much lower rate of 25 to 35 fpm when compared to LAF rates of 90 fpm. The FGI/AIA 2006 Guidelines have incorporated Memarzadeh design concepts and recommend these for ventilation parameters in surgical suites as well as other invasive procedure rooms.[30]

Understanding how the latter differs from traditional LAF systems is important as Brandt et al. recently published a multihospital study that suggested an increased risk of surgical site infection associated with LAF design.[54]Details of specific HVAC design at participating hospitals are lacking from this investigation; however, it is likely that these are the older vertical, high velocity LAF which contrasts with the newer design in 2006 Guidelines.

INFECTION PREVENTION AND CONTROL HAZARDS, IMPLICATIONS, AND INTERVENTIONS

Air Source

The following recommendations, excerpted from the 2006 Guidelines, address many of the prevention and control interventions when used in conjunction with Tables 104-2 and 104-3. Other information that describes location and design of air intakes may be useful during outbreak investigations.[1,2,3]It is possible for contaminated air to be introduced into a facility because of improper location(s) and/or height of air intakes. State codes may vary somewhat from the following minimum recommendations:

• Fresh air intakes should be located at least 25 feet (7.62 meters) from exhaust outlets of ventilation systems, combustion equipment stacks, medical-surgical vacuum systems, plumbing vents, or areas that collect vehicular exhaust or other fumes.

• The bottom of outdoor air intakes serving central systems should be as high as practical but at least 6 feet (1.83 meters) above ground level or, if above the roof, 3 feet (91 cm) above the roof level.

• Exhaust outlets (also called returns) from contaminated areas should be above the roof level and arranged to minimize recirculation of exhausted air back into the building.

• In new construction and major renovation, air supply for operating and delivery rooms should be from ceiling outlets near the center of the work area. Returns (at least two, and as far apart as feasible) should be near the floor level. Supply for nurseries, labor/delivery/recovery/postpartum (LDRP) rooms, as well as rooms used for invasive procedures, should also be near the ceiling, with returns near the floor level. Exhaust grills (returns) for anesthesia evacuation or special applications may be installed in the ceiling. It should be noted that new studies are under way indicating that velocity and direction of airflow over the surgical field may be more important than location of returns as well as ACH.[52]

• State codes and building design must be checked for use of energy-conserving mechanisms, variable air volume (VAV), and systems that may be shut down or reduce ventilation of unoccupied areas as long as patient care is not compromised.

Temperature and Relative Humidity

The supply temperature, relative humidity (RH), and filtration depend on the basic design of the HVAC (100 percent outside or recirculated air) system for the building area. Airflow rates can change with variations of temperature and humidity. The current 2006 Guidelines and 2008 ASHRAE Standard 170 provide the acceptable ranges to better address temperature/humidity combinations achievable across widely variable geographic regions (see temperature and humidity standards in Table 114-2).[30,32,33]

Air Exchange and Pressure Relationships

ACH combined with differences in air pressure assist in preventing buildup and infiltration of contaminated air. Disruptions of airflow, including propped-open doors, leakage (e.g., open windows, loose door/window seals, penetrations), and blockage of air supply/return outlets, may adversely affect air quality and balance. Consider that hospital rooms are connected by doorways, corridors, stairwells, and elevator shafts. Small pressure differences, induced by natural forces such as thermal buoyancy owing to air temperature differences or mechanical fans, can generate airflows that move air from one room to another. These airflows are very sensitive to doors or windows being kept open and can change the air pressure in neighboring rooms and corridors, reducing, or even reversing, airflow directions. This highlights the importance of keeping isolation room windows and doors closed (see Table 114-2).[9,30]

Placement of Filters within Air Handling Systems

Filter efficiencies are listed in Table 114-3; see accompanying notes on proper filter placement. The 2006 Guidelines list 90 percent filters for ORs as minimal filtration efficiency, a level considered safe for clean and sterile settings. In actuality, many ORs use 95 percent or MERV 16, but use of HEPA filters is not required or recommended. It is noted that where procedures, such as organ transplantation, may call for consideration of special design, installation should meet performance needs and be reviewed on a case-by-case basis. The only room for which 99.97 percent HEPA filtration is recommended is for a PE room for highly immunosuppressed patients (e.g., bone marrow transplantation patients, as discussed in 2003 and 2004 CDC Guidelines that address environment of care and prevention of healthcare-associated pneumonia, respectively).[1,4,30,32,33,34,35,48]

Ultraviolet Germicidal Irradiation

The role of ultraviolet germicidal irradiation (UVGI) in hospitals, clinics, and nontraditional care settings still needs further delineation. Investigations into potential use of UVGI have been numerous including work by the National Institutes of Health (NIH) that shows effective cidal effects on specific airborne bacteria such as *M. tuberculosis*.[53]Although the wavelength typically used is less effective for fungi,

UVGI may have a role in specific areas such as waiting rooms. Studies indicate that the addition of UVGI could substantially reduce the ACH necessary in the healthcare facility. However, there are operational realities such as maintenance of UVGI lamps and the need for all air at the point of planned use to be exposed for sufficient time to inactivate microorganisms. Therefore, UVGI may be applied as supplemental to the ventilation system design, rather than a primary mechanism to control airborne contaminants. Accordingly, NIH suggests that the ACH of the room should be set as if no UVGI system is installed.

The optimal relationship between ventilation and UVGI is not known. Because the clinical effectiveness of UVGI systems may vary, it is not recommended as a substitute for HEPA filtration, local exhaust of air to the outside, or negative pressure.[5]The use of UVGI lamps and HEPA filtration in a single unit offers

little or no infection prevention or control benefits over those provided by the use of a HEPA filter alone.

[55]Duct systems with UVGI are not recommended as a substitute for HEPA filters if the air from isolation rooms must be recirculated to other areas of the facility.[5]Regular maintenance of UVGI systems is crucial and usually consists of keeping the bulbs free of dust and replacing old bulbs as necessary. Recommendations from the 2003 EIC CDC guidelines only address installation:

When ultraviolet germicidal irradiation (UVGI) is used as a supplemental engineering control, install fixtures (1) on the wall near the ceiling or suspended from the ceiling as an upper air unit; (2) in the air return duct of an AII area; or (3) in designated enclosed areas or booths for sputum induction (category II).[1,5]

There is some evidence that UVGI installed inside AHUs can assist with mitigating biofouling of surfaces inside the AHU such as drip pans, cooling coils, and filter beds as well as increase operational efficiency. Definitive peer-reviewed evidence that such UVGI application is cost effective or, as claimed by some, prevents healthcare-associated infection (HAI), is not currently available.

Ventilation and Commissioning

The 2006 Guidelines[30]place new emphasis on commissioning, which is a process that verifies delivery of new construction according to contract specifications, before it is accepted by the owner. Commissioning for ventilation equipment requires identifying "acceptance criteria" permitting verification of critical ventilation specifications for air balance and filtration before the owner accepts "delivery." There must be some means to ensure that the system is delivering air quality according to specifications. The use of electronic monitors or particle counters to measure total air particulates is one means to provide this type of measure at the time the project is turned over to the owner. This method is being considered more frequently but is not considered routine testing.

No current recommendations or regulations exist regarding frequency for checking effectiveness of filters. One source suggests 6 months of checking as reasonable, and another strongly suggests certification and recertification of OR HVACs and filtration systems.[11,37]TJC, in their 2009 EOC standards, state that the [facility] "identifies in writing inspection and maintenance activities for all operating components of utility systems" and "identifies in writing the intervals for inspecting, testing, and maintaining all operating components of the utility systems on the inventory, based on criteria such as manufacturers' recommendations, risk levels, or hospital experience."[31]However, monitoring the need to change or clean filters more frequently is important during new construction or renovation (see).

INFECTION PREVENTION AND CONTROL

Policies

The construction/renovation policy, as outlined in , addresses issues affecting ventilation. An effective policy should do the following:

• Incorporate key design elements to ensure that departments affected by HVAC system replacement or modifications are involved in planning before new construction or major and minor renovation.

• Establish authoritative contingency plans and include processes for rapid communication when/if closures are required during construction, renovation, or power losses affecting HVAC shutdowns and startups. (See , for a complete discussion of an ICRA, and **120. Infectious Disease Disasters: Bioterrorism, Emerging Infections, and Pandemics**.)

• Ensure that checklists consider some or all of the following during planning of new construction and planning during repair/renovation or other required remediation activity. Testing frequencies for new or current systems should be determined by facility-specific needs and data, but a scheduled plan of testing should be documented:

• Location of intakes and returns

• Use of outside or recirculated air

• Number of air changes and proper balancing

• Filters (number and percent efficiency for different sites)

• Accountability for and frequency of testing of ACH and pressure

• Specific temperature and humidity limits triggering limited use of a work area

• Contingency plans in the event of power interruptions, contamination, and/or damage to HVAC systems. (See **112. Maintenance and Engineering**, and **107 Environmental Services**.)

• Preventive maintenance and/or cleaning of ductwork, vents, and/or induction units. (See **112. Maintenance and Engineering**.)

• Disposal methods and procedures for removal of used air filters. (See **112. Maintenance and Engineering**, and **113 Waste Management**.)

Utility management policies, as required in TJC EOC standards, should include infection prevention and control input to prevent, detect, and reduce risk from infectious hazards. In regard to general HVAC contamination, it is critical to clean and/or replace filters if they are affected by water disruptions or flooding conditions that support fungal growth and contamination of the air supply. Recommendations for problems resulting from flooded or contaminated ventilation components (e.g., contaminated ceiling tiles) are given in . When power is reestablished after a power interruption, and dampers and fans resume operation, dust released during this process may transmit infectious agents to patients and staff. Policies or protocols should address issues including: communication, operating the HVAC for some specified time to clear the ducts, followed by immediate cleaning before putting area (e.g., OR) back into service, and documentation of completion. Long-range follow-up includes surveillance of airborne infectious agents and/or HAIs.[31](See Chapters **112 Maintenance and Engineering**, and **116 Construction and Renovation**.)

ENVIRONMENTAL MONITORING

Detection and identification of certain HAIs may suggest HVAC malfunction (e.g., healthcare-associated TB, single cases of aspergillosis in severely immunosuppressed patients, healthcare-associated varicella infections). Analysis of postoperative surgical site infection rates and associated infectious agents may offer important clues to problems in the OR air system(s).[6,14,23,25,26,56,57,58,59,60]

• Visual monitoring: Visual monitoring of processes established for construction, renovation, or maintenance procedures is an important method for reducing the potential for infection from airborne contamination. (See .)

• Specifications and commissioning: Contracts should certify to an owner's satisfaction that all specifications of HVACs have been met. Contracts should include outcome criteria that were met using

specific measures.[1,2]

• Environmental air sampling and culturing: Sampling protocols and procedures in actual disease outbreaks are well substantiated.[1,2]

• Routine microbiologic surveillance: Use of routine microbiological sampling and culturing has not been recommended except as an integral part of an epidemiologic investigation. There is no clear answer for initiating environmental surveillance in the absence of actual or pending problems.[1,5,61,62]

Outbreak Investigation and Culturing

When an outbreak is identified or suspected, an environmental source may be present and confirmatory testing is appropriate. (Also see **12. Outbreak Investigations**.)

A critical review of the indications for airborne particulate monitoring or cultures must be done in light of basic principles of outbreak investigation (e.g., establishing that an outbreak exists). One may also consider the following guidance:

• Purpose of culturing and appropriate methods should be identified beforehand.

• Decisions and planned actions regarding results of culturing should be anticipated before undertaking the process.

• Determination should be made whether there are existing standards to interpret results.

Air Standards

Air standards have been developed for "clean rooms" in industrial settings but do not have general applicability in healthcare settings, as outlined in ASHRAE's 1999 publication, *Clean Spaces*.[32]The final publication of the USP-797 standard on compounded sterile preparations (CSP) describes an ideal ventilation design for pharmacies. The chapter, as of June 2008, was incorporated into USP 31/NF 26 and requires minimally the use of an ISO Class 5 laminar flow workbenches for compounding. It also acknowledges the lack of standards for interpreting air quality control testing results, and refers to the CDC-EIC Guidelines on environmental sampling and testing.[1](See **110. Pharmacy Services**; see Supplemental Resources.)

Bioaerosol Standards

Absolute standards for airborne fungal spores or other bioaerosols do not exist. Many studies have measured airborne contamination, but establishing specific levels that correlate with actual disease has proved challenging given the ubiquitous nature and variety of airborne fungi.[13,63,64,65,66,67,68,69,70]Lower levels of spores have been associated with lower incidence of disease, but no one has established a "safe" level of exposure.[63]Rhame has suggested that spore counts be kept as low as possible hospitalwide, with extreme measures reserved for bone marrow transplant patients.[57,60]More recently, Falvey and Streifel were not able to demonstrate that routine monitoring of air for fungi could reliably predict cases of invasive fungal disease and instead concluded that maintenance of filtration and other methods to minimize environmental contaminants were more effective.[71]

Relative Threshold

Given the lack of absolute standards, there is general agreement that thresholds specific to a facility or area need to be established based on local, facility-specific experience. It is important that any indoor measurement also use outdoor levels for comparison as well as from other areas inside the facility that are not the focus of a particular problem investigation.[1]

MICROBIOLOGICAL ENVIRONMENTAL SAMPLING AND CULTURING METHODS

If airborne fungal spore monitoring is necessary, a variety of sampling techniques may be considered (e.g., volumetric air sampling).[1,23]Detection of fungi such as *Aspergillus*species may require further investigation into design (air intakes), proper equipment functioning (fans and filters), or proper equipment maintenance.[22,64]One key step in interpreting results is comparing fungal spore counts from outdoor air to those levels obtained from indoor air samples. Given the filtration systems in place, elevated levels indoors might suggest amplification from a contaminated reservoir.

The type of sampling device and methodology for measuring total particulates, bioaerosols, or selective media for culturing fungi also will vary. The need for typing or "fingerprinting" specific isolates must also be considered.[1,4,23]Electronic monitors or particle counters may be useful to provide information on general levels of dust and contamination; care must be taken to distinguish between total particulates and viable bioaerosols. Measuring total airborne particulate matter (as opposed to microbiological culturing) may be used in the commissioning process for ventilation systems as addressed in the 2006 Guidelines. One current review of monitoring equipment and parameters to be considered for sampling includes a procedure often used in aspergillosis outbreaks.[24]The 2003 CDC-EIC Guidelines provides a comprehensive summary on various approaches to sampling.[1]

Planning Checklist for Environmental Surveillance Strategy

1. Determine plan and purpose of surveillance to guide prevention and interventions.

2. Review the literature for published information for values that may assist in establishing a baseline or threshold.

3. Establish your own facility-specific baseline or threshold experientially, and identify the degree of variation acceptable as a baseline (i.e., a value or range of values).

4. Determine the actions or interventions that will be taken if values are exceeded.

5. Ensure that the microbiology laboratory is involved in the plan. Most clinical microbiology laboratories are not equipped to isolate microorganisms from environmental sampling. Individuals collecting such samples should utilize a laboratory that is certified or has capabilities in environmental microbiology.

6. Determine sampling methods and culturing techniques that are appropriate for the event.

7. Ensure that collecting/sampling personnel are trained for consistency, especially with air-sampling devices. Consider budgeting for services of an outside expert consultant.

8. Conduct the sampling and quantify results (i.e., number of colonies per unit).

9. Determine if values exceed the established threshold described in item 3.

10. After analysis and communication, follow the action plan determined in item 4.

In summary, decisions regarding environmental sampling and culturing must be part of a planning process and must be laid out before undertaking the process. The methods and process used should be appropriate for the occasion. Surveillance cultures are unlikely to provide useful information to prevent or control airborne or construction-associated infections unless the standards or baseline values needed for interpretation are clearly identified. Collaboration with microbiology laboratories for sampling techniques and/or culture interpretation is essential. (See **107. Environmental Services**.)

Specific Applications

Ventilation issues for each of the following areas should consider outside versus recirculated air, number of air changes, air pressure relationships, and filtration efficiencies.

Common Waiting Areas

Considerations include temporary location areas with appropriate air pressure for patients with possible airborne infections (e.g., TB) away from other occupants or protection of severely immunosuppressed patients from others. The infection preventionist should use a facility-based risk assessment when considering need and optimal location of a negative-pressure treatment room with air that is exhausted to the outside or through a HEPA filter before recirculation in common waiting areas. The 2006 Guidelines require the emergency department and radiology waiting areas be in negative pressure with respect to adjacent areas.[30]

Surgical and Critical Care Units

Provisions should be made for All room(s) as well as rooms for managing severely immunosuppressed patients, depending on program needs.

Operating Rooms and Cardiac Catheterization Laboratories

Positive pressure, ventilation, and filtration rates are similar for all areas where invasive procedures are performed as described in the 2006 Guidelines.[30]In each, air should flow out of the room and the minimum ACH should be 15, with three of these ACH being fresh or outdoor air. The air should be filtered with an efficiency of at least 90 percent (see Table 114-3). The optimum method for managing patients with active TB requiring urgent surgical intervention has not yet been determined. However, the following principles should be followed:[1,5]

• The number of air changes provides increased dilution of potential contaminants. Charts published by NIOSH are included in the 2005 CDC TB guidelines and may assist in calculating the percentage of particles removed by time and ventilation rates. These charts can be helpful for determining the time needed before resuming use of an OR after a≈procedure on a patient with confirmed or suspected active TB disease.[5]

• Modifying the pressure relationships of the OR to neutral or negative is not recommended and could disrupt pressure balance, and has not been studied for effectiveness.

• Supplemental filtration devices, if deployed inside the OR, should be turned off during the surgical procedure.

• If a surgical suite or an OR has an anteroom, the anteroom should be either (1) positive pressure compared with both the corridor and the suite or OR (with filtered supply air); or (2) negative pressure

compared with both the corridor and the suite or OR.

• Intubation and extubation location for the known/suspected TB patient should be considered. Scheduling of patient procedure (e.g., last case), masking of patient during transport and before intubation, and performing extubation in a room meeting AII ventilation requirements may be used to reduce risk of transmission.

• Extubate and allow the patient to recover in an AII room.

A recent study using submicron particles and smoke plume to mimic behavior of airborne *M. tuberculosis*if encountered in the OR found a portable anteroom-HEPA unit was much more effective in containment of airborne particles than portable HEPA devices placed inside the OR; in addition, the latter were also found to disrupt airflow patterns.[72]

Bronchoscopy/Endoscopy Treatment Rooms

Bronchoscopy procedures for persons known or suspected to have pulmonary TB should be performed in treatment rooms meeting AII room ventilation requirements. The bronchoscopic procedure often results in copious and productive coughing postprocedure; and recovery for known/suspected TB patients should be carried out in a room meeting AII ventilation requirements as well. Other measures such as having the patient wear a mask during transport, minimizing waiting times in common areas, and supplying tissues and disposal bag to patient are recommended. The 2006 Guidelines distinguish endoscopy from bronchoscopy room ventilation and recommend negative airflow and total air exhaust for bronchoscopy; negative pressure for endoscopic rooms is indicated as well. However, as indicated in the footnotes to the 2006 Guidelines Table 2.1-2, this is intended for odor control, and may vary according to need. Negative pressure is already required for the instrument decontamination/reprocessing area (see Table 114-2 and 2006 Guidelines Table 2.1-2).[30]

Protected Environments for Immunosuppressed Patients

Highly immunosuppressed patients (i.e., those with prolonged, severe granulocytopenia, most notably bone marrow recipients, possibly solid organ transplant recipients, and patients with hematologic malignancies receiving chemotherapy) require protected environments to reduce the risk of infectious complications. Such environments provide positive-pressure ventilation where the amount of HEPA-filtered air exceeds the amount of air exhausted by at least 10 percent. Effective protected environments require a "bundle" of elements—not just HEPA filtration. Other elements include highly filtered air (≥95 percent efficiency for 0.3-micron particles), increased room air exchanges (≥12 ACH), a sealed room, and airflow direction from the patient toward the corridor. Some facilities use LAF rooms for bone marrow transplant patients; such rooms provide directional airflow with more than 100 ACH. LAF rooms are expensive and their cost-effectiveness is somewhat controversial; therefore, many facilities use other ventilation systems for such patients.[4’15’56’73]

General Patient Care Units

These areas require minimum ventilation and filtration requirements as specified in the FGI/AIA Guidelines (see Tables 114-1 and 114-2 or FGI/AIA Guidelines Tables 7-2 and 7-3).[30]

Airborne Infection Isolation Rooms

AII rooms and PE, if needed, require, at minimum, a private room with tight sealing to prevent air infiltration to or from the room. Anterooms are not essential to maintain negative air pressure, but may

be useful depending on facility design. Isolation rooms should not be designed with reversible airflow because of patient/HCP safety considerations as well as maintenance of the system. The FGI/AIA guidelines recommend 12 ACH in new facilities or those undergoing major renovation. Older facilities may only be able to achieve 6 to 12 ACH, but use of supplemental HEPA devices can increase the number to 12. As noted earlier, one study found that a balanced ventilation system does not guarantee inward airflow direction.[47]It was determined critical to employ devices that provide visual demonstration of the direction of airflow (e.g., smoke trails, flutter strips) in addition to continuous or built-in air monitors. The need for routine monitoring of AII rooms is highlighted in a recent investigation. Saravia et al. studied pressurization of 678 AII rooms in a large number of hospitals in the United States and found only 32 percent met recommended negative pressure differential; 9 percent, ironically, were found to be in positive pressure.[74]A major factor for this suboptimal performance was leakage of the AII rooms studied. Some additional recommendations on design of AII rooms are available elsewhere.[75]

Ancillary Support Areas

For food service, diagnostic imaging and treatment rooms, sterilizing and cleaning supply/distribution areas, and other service areas, see the 2006 Guidelines. Clean support areas generally require 10 ACH with airflow out of the area (positive pressure). The 2006 Guidelines recommend six ACH and minimum air filtration efficiency of 90 percent for general diagnostic and treatment rooms.[30]

General Room Design and Maintenance

Issues include identifying intakes and returns, ensuring routine cleaning, and monitoring according to type of area.[26]The use of ceiling fans in certain rooms such as LDRP or modern "birthing rooms" has been questioned but is not specifically addressed in the 2006 Guidelines. State regulators usually determine if permissible; some states do not allow ceiling fans, based on a perception of the inability to control dust.[2,37]The use of supplemental fans in patient care areas requires thoughtful consideration of many factors such as mitigating disruption of dust, cleaning of fan blades, compliance with facility electrical safety requirements, and noise. In general need for supplemental fans should be temporary, as a properly working HVAC should provide for comfortable conditions. Even with their use it is unlikely these will alter room pressurization and normal relationships between areas.

Conclusions

In summary, issues of ventilation have major impact in healthcare today as emerging pathogens and bioterrorism force new attention to ventilation and the health of building occupants. Table 114-1 illustrates a number of outbreaks associated with better-known airborne contaminants that also are serious health hazards. Even though Tables 114-2 and 114-3 are design specifications, they provide the needed guidance for measuring ventilation expectations of specialty areas for evaluation. Hopefully better understanding the ventilation systems and associated risks will reinforce the importance of early input of infection prevention into planning and prevention rather than remediation efforts resulting from poor design and maintenance.

Future Trends

A number of issues and concerns remain and require continual research and evaluation for methods to improve patient outcomes. Some include the following:

• Surge capacity: Addressing ventilation when facilities need to increase surge capacity in response to bioterrorism or major outbreaks of airborne infectious agents.

• Fans: Concerns have been raised regarding use of fans in patient care areas. No studies or regulations have directly addressed whether fans affect health outcomes.

• Ventilation and pressure relationships: Whereas the need for negative air pressure is clear, new studies are needed to determine the ideal room pressure differential related to actual infectious agent transmission and risk for developing actual disease. This is an area beginning to be addressed.

• Ventilation duct cleaning: The efficacy of vacuuming or sanitation of ventilation ducts to enhance IAQ or prevent disease transmission is yet to be determined.

• Alternative HVAC designs:

• Displacement ventilation. Recently there has been a renewed interest in alternatives to traditional HVAC design that aim to supply sufficient filtered air at the ceiling and return via ducts either in the ceiling or at locations in the wall around an enclosed space, such as mixing ventilation (MV). One alternative is displacement ventilation (DV). DV depends on the principle of differentials in temperature to move contaminants from an enclosed space. Cool, conditioned air is supplied at floor level and because warm air rises, the exhaust or returns are located in the ceiling. There is little in-use experience for this design relative to assessing its comparative effectiveness of DV to MV relative to containment of airborne or droplet-transmitted microorganisms, particularly in healthcare settings. One investigation did suggest this be approached cautiously in patient care areas as there was dissemination of contaminants horizontally from a patient lying in a bed in a room with DV using manikins with smoke plume for surrogate of airborne agents.[76]Others using CFD models also question efficacy of DV.[77]Those interested in more details are referred to a review by Tang et al.[9]

• Natural ventilation (NV). NV has been in place for decades. This may be all that is available in hospitals in developing countries where electrical power and utility resources severely limit mechanical systems. For United States-based facilities, other major limiting factors are extremes and variation in weather conditions. These preclude opening windows to outdoor air, for example, in Michigan hospitals in the middle of January. Also, design of mixing ventilation is optimal if the building envelope is sealed tightly, including windows. For the latter buildings, open windows can significantly alter room pressurization, energy demands on the HVAC system, and most importantly bypass existing filter media in the AHUs. Some have reported that NV is effective in removal of contaminants in settings where resources are constrained or nonexistent, such as caring for those with TB disease in Lima, Peru—but the building design is critical in even these situations.[78]

• Sustainable energy utilization and stewardship of the environment: HVAC systems require considerable energy to operate and maintain. With growing appreciation and concern over stewardship of the global environment there is considerable attention and study of alternative designs and other interventions that can support more efficient use of energy. The delicate balance is how to accomplish better efficiencies without compromising safety of patients or other occupants in healthcare facilities. At present, there are few published studies demonstrating how to maintain this balance but additional research projects and experience of providers are ongoing. Those interested in more are referred to new organizations,

Practice Greenhealth and Global Health and Safety Initiatives, which are facilitating an environmentally supportive agenda. (See Supplemental Resources.)

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Water Systems Issues and Prevention of Waterborne Infectious Diseases in Healthcare Facilities

Author(s): Linda Dickey, RN, MPH, CIC
Director, Epidemiology & Infection Prevention

UC Irvine Health
Orange, CA

Published: October 3, 2014

Abstract

This chapter addresses waterborne pathogen risks in healthcare settings and strategies for infection prevention and control. Waterborne pathogen risks can be significant in healthcare settings, from unexpected incidents of intrusion of water into occupied areas to mitigation of microbial contamination. As a result, water-related problems are among the most challenging infection prevention issues involving the environment of care. Prominent among these is prevention and control of Legionella*contamination of water distribution systems, which is discussed here. However,* Legionella *risks vary by geographic region, and* Legionella *is just one of many other microorganisms, including fungi, that can be present in the water distribution system. This chapter attempts to provide an overall approach to assessing risks and developing prevention strategies, including design considerations, routine preventive maintenance for operations and equipment, and remediation measures during floods or utility outages. Water disinfection/treatment options are also discussed, including considerations for use and strengths and challenges of various modalities.*

Key Concepts

• Water delivery systems are an essential component of the environment of care in healthcare facilities that are dependent upon maintenance of water quality standards employed by the community public water supplier, typically a municipality in the region of the healthcare facilities. This responsibility for water quality then transitions to the facility once water enters the facility water distribution infrastructure, reflecting complementary roles for prevention.

• Waterborne bacterial and fungal contamination risks are often subtle and associated with a wide variety of sources and have potential for direct or indirect transmission. Understanding conditions that allow for waterborne pathogen growth and proliferation is critical to prevention and control. Infection preventionists need to maintain a high level of awareness for infectious agents that might be causing waterborne infectious diseases in the population they serve. This includes awareness, surveillance, and reporting of community-associated diseases to the appropriate local public health agency; diseases associated with moisture and water-distribution systems that may be facility-associated also must be reported.

• Key prevention strategies for waterborne pathogens include facility risk assessment for areas of potential growth and/or transmission, use of design strategies aimed at reducing the risk of pathogen growth or release, compliance with maintenance practices that contribute to controlling transmission risk, employment of remediation measures during emergencies, and consideration of disinfection modalities when surveillance or risk assessment indicates a need.

• *Pseudomonas*spp., atypical (or nontuberculosis) mycobacteria, and *Legionella*are the most commonly reported waterborne pathogens.

• Water-associated disease has also been reported in the community-based personal care services industry, highlighting the importance of infection prevention in nontraditional industries.

Background

The impact of water-related contamination on health in any setting is far reaching, and consideration of water issues is an essential component of infection control risk assessment (ICRA) as described in . Design engineers and architects increasingly recognize that proper planning and design have a major influence on preventing contamination of water distribution systems and reducing potential infection risks for patients, residents, and healthcare personnel (HCP). Therefore, a basic understanding of key terms, concepts, and effects on patients and HCP is essential to providing appropriate input to ICRA.

Key resources for the infection preventionists (IPs) that address water-related problems and preventive solutions include the 2003 Centers for Disease Control and Prevention (CDC) and Healthcare Infection Control Practices Advisory Committee (HICPAC) Guidelines and Recommendations for Environmental Infection Prevention in Healthcare Facilities (referred to hereafter as CDC-EIC guidelines), the 2010 Guidelines for Design and Construction of Health Care Facilities, and a resource from the Association for Professionals in Infection Control and Epidemiology, Inc. (APIC) titled *Construction and Renovation: Toolkit for Professionals in Infection Prevention and Control.*1–3Although planning must necessarily provide for remediation in the event of disaster—natural or manmade—the key to prevention is proactive risk assessment, thoughtful design, and routine preventive maintenance. These concepts are systematically reviewed in this chapter for water systems and fixtures and other equipment used in healthcare facilities (HCFs). At the end of this chapter are supplemental resources that may be helpful when conducting facility risk assessment or reviewing design considerations during construction.

Basic Principles

TERMINOLOGY

The following terms may prove helpful to understanding some types of water within healthcare settings:

*Black water:*Waste water containing sewage contaminants

*Deionized water:*Purified water that has had charged ions removed. Used for various applications within healthcare, including the laboratory.

*Gray water:*Water (as from a sink or bath) that does not contain serious contaminants (as from toilets or diapers).

*Potable water:*Water suitable for drinking.

*Reverse osmosis water:*Water forced through a special membrane under pressure, which produces highly purified water. Typically requires remineralizing with essential trace elements before use. Used for various applications within healthcare, including in dialysis.

BASIC PLUMBING DESIGN

Documented outbreaks have been associated with splashing back from sink drains containing contaminated biofilm, aerosols from shower heads, and contaminated potable (tap) water used with patient care equipment or directly with patients. IPs should understand the basic design of a water supply and waste system to provide effective input regarding plumbing system design and to understand potential factors that may contribute to suspected waterborne infections.

WATER QUALITY

Multiple factors contribute to the quality of water in a HCF, including the methods of treatment used in the municipal water supply prior to the water coming into the facility. For example, in a 2-year, prospective environmental study in San Francisco, monochloramine was shown to reduce building *Legionella*colonization from 60 percent before treatment to 4 percent after treatment. Factors affecting increased *Legionella*colonization in San Francisco buildings included locations over 10 stories high, locations with interruptions in water service, and buildings with water heater temperatures <50°C.4HCFs may obtain an annual report from the local water utility that provides updated information on water treatment and quality. This information could be helpful when performing an annual facility risk assessment for waterborne pathogens.

Drinking water quality also depends on preventive maintenance and surveillance for healthcare-associated infections (HAIs), including a high index of suspicion for infectious agents associated with moisture and water distribution systems.

Water-Associated Infectious Agents

Bacterial and fungal contamination risks are associated with potable (drinking) water. Microorganisms associated with water include *Pseudomonas, Acinetobacter, Moraxella, Aeromonas, Xanthomonas, Legionella, Aspergillus, Fusarium*spp., and atypical (nontuberculosis) mycobacteria.5–8All of these genera are associated with serious disease and can potentially be transmitted directly or indirectly from faucets and sinks or through inhalation of aerosols, such as those generated from construction activities or from showerheads.5However, based on limited quantifiable data, the risk of healthcare-associated transmission of these pathogens from water is considered relatively low.5,9(See **77. Environmental Gram-Negative Bacilli**and **84. Legionella pneumophila**.)

When disease transmission from direct contact with waterborne microorganisms is considered, *Pseudomonas*spp., atypical mycobacteria, and *Legionella*are the most commonly reported pathogens

identified. Furthermore, *Pseudomonas*and atypical mycobacteria often are related to contaminated equipment. For example, water bottles improperly filled with tap water and used for rinsing tracheal suction tubing resulted in an outbreak of *P. cepacia*.10Tubing that was permanently attached to showers and used for irrigating patients in a burn unit was implicated in a serious outbreak of *P. aeruginosa*bloodstream infection in five patients.11One letter to the editor noted an antidotal outbreak of *Chryseomonas meningosepticum*on a neonatal intensive care unit (ICU) associated with bathing infants with tap water.12

Contamination from atypical mycobacteria has led to many investigations of both true and pseudo-outbreaks. The frequency of nontuberculocidal mycobacteria (NTM) in potable water at a large trauma hospital was examined, showing that out of 69 water samples, 36 harbored NTM despite chlorine levels being within the range required by local guidelines.13A comprehensive review of both types of outbreaks caused by atypical mycobacteria has been published.14For example, an outbreak of postsurgical nasal cellulitis due to *Mycobacterium chelonae*resulted from inadequately sterilized surgical equipment.15Inadequate sterilization and rinsing of surgical instruments with contaminated potable water, the source for which was likely biofilm inside the piped water system, were factors for a cluster of cutaneous infections caused by *M. chelonae*following liposuction.16Others have reported on the financial burdens of pseudo-outbreaks, such as *M. gordonae*from water used during bronchoscopy, that led to unnecessary treatment and isolation of patients suspected of having *M. tuberculosis*.17Water-associated disease has also been reported in the community-based personal care services industry, demonstrating that microorganisms can cause outbreaks outside of healthcare delivery settings. These reports highlight the importance of infection prevention in nontraditional industries and in healthcare.18Infection prevention guidelines for this sector have been published (e.g., Health Canada's Practices for Personal Services: Tattooing, Ear/Body Piercing, and Electrolysis19and Infection Control Guidelines: Foot Care by Health Providers20).

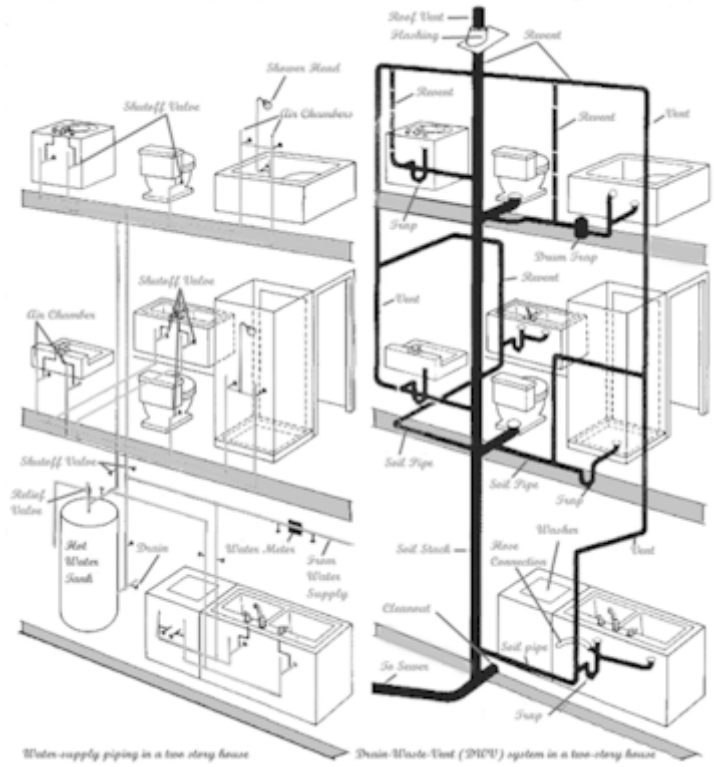

Figure 115-1.

Basic plumbing supply and wast View Image

Inhalation of aerosols of contaminated water is the primary mechanism of transmission for *Legionella*, not person-to-person transmission (also see **84. Legionella pneumophila**). Outbreaks of *Legionella*associated with contaminated equipment often involve inhalation of contaminated aerosols. For example, two cases of healthcare-associated legionellosis in an ICU were reported to be associated with aspiration of nasogastric feedings diluted with tap water.21After a healthcare-associated case of *Legionella*at one Japanese hospital, an environmental investigation revealed that a steam towel warmer was contaminated with *Legionella*. Although the index case was not definitively linked to the towel warmer as the source, the authors note that the water in the apparatus may have served as a reservoir for *Legionella*and recommended draining, cleaning, and drying of the device.22

Other microorganisms, including fungi, have health consequences and are discussed in the consideration of environmental sources of water-associated infectious agents. See Table 115-1 for selected examples of microbial contamination of water systems and interventions in HCFs.10,23–34Outbreaks associated with aerosols generated from multiple sources of water in institutional settings are fully addressed. The 2004 CDC guidelines on the prevention of pneumonia and the CDC-EIC guidelines provide a comprehensive discussion of the impact of waterborne opportunistic pathogens in healthcare settings.1,35

Table 115-1 Examples of Microbial Contamination of Water Systems and Interventions

Author, year (reference)	Organism	Population/Location	Epidemiologic Factors	Remedial or Preventive Measures
Crane et al., 198110	*Pseudomonas paucimobilis*	ICU	Contaminated tap water	Thermal decontaminated system; revised procedures for tap water use equipment
Burns et al., 199123	*Mycobacterium fortuitum*	Alcoholism rehab unit	Ward showers; tap supply	Disconnected and disinfected showers
Sniadack et al., 199324	*M. xenopi*	Hospital rooms	Water supply (pseudo-outbreak)	Maintain temp >120°F (49°C; ideal 54°C)
Prodinger et al., 199425	*Legionella pneumophila*serogroup 1	Renal allograft	Water distribution system	Replaced central water supply with individual room electric water heaters
Bangsborg et al., 199526	*L. pneumophila* serogroups 1 and 6	Heart-lung transplant	ICU kitchen ice machine	Disinfected machine; preventive maintenance
Graman et al., 199727	*L. pneumophila*serogroup 6	Patient receiving ventilation	Ice machine	Replaced supply line and treatment water system
Kool et al., 199828	*L. pneumophila, Legionella*spp.	Transplant center	Water system	Hyperchlorinated supply
Biurrun et al., 199929	*L. pneumophila* serogroup 6	General hospital	Water distribution system	Copper-silver ionization treatment; continuous chlorination system
Kappstein et al., 200030	*Acinetobacter junii*	Pediatric oncology	Contaminated aerators	Removed, used aerators with radially/vertically arranged lamellae
Darelid et al., 200231	*L. pneumophila*serogroup 1	General hospital	Water distribution system	Maintained water temperature 55°C
Anaissie et al., 200232	*Aspergillus*spp.	Bone marrow transplant	Concentration of airborne fungi on shower surfaces	Cleaned shower floor with detergent prior to use of shower
Nasser et al., 200433	*Burkholderia cepacia*	General hospital	Tap water used to dilute alcohol skin antiseptic	Implemented single-use alcohol swabs

Hota et al., 200934	*Pseudomonas aeruginosa*	ICU and transplant unit	Biofilm inside drain and design of hand-washing stations inside patient rooms	Hand-washing stations were redesigned to prevent splashing
Lowe	Extended-spectrum B-lactamase-producing *Klebsiella oxytoca*	General hospital	Biofilm inside drain and design of hand-washing stations inside patient rooms	Change in sink cleaning regimen, sink drain modifications, antimicrobial stewardship
Kotsanas	Carbapenem-resistant Enterobacteriaceae (CRE) *K. pneumonia, S. marcescens, E. cloacae*	Intensive care unit	Sink grating and drains	Cleaning and decontamination attempts unsuccessful; plans for sink replacement
Lucero	*B. cepacia*	Outbreak among ventilated pediatric patients	Hospital tap water used during oral and tracheostomy care	Change in clinical process

Environmental Sources Of Water-Associated Infectious Agents

As noted, various types of equipment and fixtures can promote the growth of water-associated pathogens. Important water reservoirs for these organisms include potable water systems and cooling towers, flush sinks, faucet aerators, hoppers and toilets, eyewash/drench shower stations, chests/ice machines, water baths used to thaw or warm blood products and other liquids, and whirlpool or spalike baths.5–10,36–40Concern has been raised about water from flower vases as a disease risk for immunosuppressed patients because potential pathogens have been isolated from such water sources. However, actual disease transmission from these sources has not been well documented and likely occurs rarely. The CDC-EIC guidelines recommend no restrictions for immunocompetent patients. However, equipment may become vehicles of pathogen transmission if it is rinsed with tap water, becomes contaminated, and comes in direct contact with mucous membranes or nonintact skin. The CDC strongly recommends eliminating water/fluid reservoirs whenever possible as an overall guiding principle.1

WATER DISTRIBUTION SYSTEMS, COOLING TOWERS, AND ENVIRONMENTAL SURFACES

Sources of aerosolized water, especially cooling towers, can promote the growth and dispersion of *Legionella*. Once *Legionella*is introduced into a facility's potable water system, organisms may proliferate in the heated water reservoirs, spread throughout the water distribution system (i.e., pipes), and ultimately contaminate sink faucets and showerheads.41,42One report also identified dysphagia as a risk for legionellosis in a postoperative patient—the source for which was contaminated ice—and appeared to involve exposure to a very high dose.43Facilities typically have more extensive, dedicated water treatment and delivery systems for those needing hemodialysis, which is addressed elsewhere.1(See **39. Dialysis**.)

Other microorganisms have been reported to cause problems in the water distribution system. For example, an outbreak of group A streptococcus that spread through a maternity unit was ascribed to a handheld showerhead.44

Excessive moisture around pipes and insulation, condensation in drain pans, and flooding from broken pipes can lead to extensive environmental fungal contamination. Such contamination has been associated, for example, with *Penicillium*spores released from water-soaked and rotted cabinets around sinks.45,46Other moisture-prone surfaces that can cause problems include air-handling units and ventilation ducts. For example, a report of fungal endophthalmitis from *Acremonium kiliense*demonstrated that contaminated water in a humidifier served as a reservoir, with subsequent spread of the fungi through the air handler.47

Static (stagnant) water systems can serve as reservoirs of organisms in the healthcare environment by supporting bacterial growth.48–51When water is not moving in recirculation loops, it becomes stagnant, and the residual chlorine or other water treatments can dissipate and lose antimicrobial activity. This in turn leads to corrosion (scale and sediment) and development of biofilm that further amplifies the growth of microorganisms, particularly *Legionella*. Stagnation may result from poor design (dead legs or capped pipes left in place when an older system is renovated) or from a power loss causing pump failure, with resultant loss of water flow. Water in such systems can cause direct or indirect spread of microorganisms to patients. For example, one outbreak occurred after a water pump failed; when water pressure was restored, *Legionella*had multiplied in the water system to considerable levels.52

Anaissie and colleagues6,8,40investigated risks of fungal contamination of hospital water systems. *Fusarium*spp. in water have also been studied by Raad et al.,7who failed to find a source within water systems in the facility and instead concluded that the majority were community associated. These conflicting reports highlight the need for careful epidemiologic investigation of potential sources by the IP.

Another investigation by Anaissie and colleagues32focused on the risk of secondary aerosolization of fungi from the wall and floor surfaces of shower facilities in a bone marrow transplant unit. The authors attempted to show an association between the cleaning of water-related environmental surfaces before patient use and a reduction in the airborne concentration of medically important filamentous fungi in a hospital ward housing immunocompromised patients.

DECORATIVE WATER FOUNTAINS, WATER WALLS

As organizations recognize the importance of care delivery sites as therapeutic environments, they may consider installation of features such as decorative water fountains, water walls, or other water features. Mounting evidence has clearly shown that open water features such as decorative fountains and water walls may aerosolize waterborne pathogens and can present an infection risk in healthcare and nonhealthcare settings. In 1992, one of the earliest published outbreaks of *Legionella*occurred at an Orlando, Florida, hotel: five persons developed legionellosis, and all five reported exposure to a decorative water fountain in the hotel lobby. *Legionella pneumophila*was recovered from the fountain and found to match one clinical isolate through pulsed field gel electrophoresis (PFGE). Poor maintenance and underwater lighting, which contributed to ideal water temperatures for *Legionella*, were noted as contributing factors.53Another community outbreak resulting in 18 cases of Legionnaire's disease was associated with exposure to a small restaurant fountain; of note, the fountain was without obvious aerosol-generating capability. The outbreak ceased with removal of the fountain.54A water fountain in a radiation oncology therapy unit resulted in transmission of *Legionella*to two patients receiving cancer care in the unit. Despite being equipped with water filtration and an ozone generator and records indicating routine maintenance, the design of the fountain allowed for areas of water stagnation, likely contributing to pathogen growth.55Another outbreak involving a water wall in a hospital lobby resulted in eight cases of legionellosis; all individuals were either outpatients or visitors to the facility. Routine maintenance was again noted; however, design features of the water wall likely

contributed to the growth of *Legionella*.56The predominance of evidence for risk involves indoor, open features; however, outdoor fountains may also present a hazard. One paper describes an outbreak of *Legionella*among eleven individuals exposed to an outdoor decorative fountain while attending a local rock concert; a case control study implicated the fountain as the likely source.57

SINKS, FLUSHING RIM SINKS, HOPPERS, AND TOILETS

Sinks and related fixtures may pose health risks because contamination of sink drains or faucet aerators is expected. However, the more important risk may be from splashing contaminated water onto patients or supplies, which can lead to exposure to patients or contamination of supplies and equipment. Reports of direct disease transmission are rare; one of the earliest published reports describes an outbreak caused by *P. aeruginosa*traced to a delivery room resuscitator.5Faucet aerators on sinks can enhance growth of waterborne organisms. A published review of pertinent literature reports that two patients in an ICU became colonized or infected with *Stenotrophomonas maltophilia*after exposure to contaminated faucet aerators. Aerators are not recommended, but if they must be used, especially in an area with immunocompromised patients, a systematic cleaning routine should be established (see further discussion below on aerators and laminar flow controls).15,58Poorly maintained sink traps might also be reservoirs for microorganisms if splashing is not controlled.51Proper sink design and appropriate preventive maintenance may reduce or eliminate these concerns. Indeed, a recent outbreak of infections caused by *P. aeruginosa*in an ICU and transplant unit identified a reservoir of the strains that matched those from patients in a biofilm in hand-washing sinks inside the patient room.34However, the mechanism of transmission had more to do with a hand-washing sink design that included a shallow basin, close proximity to point of care, and water that splashed from the sink to surfaces around the sink as much as 1 meter away. Several other reports have also associated sinks with waterborne pathogen transmission, including one paper noting 15 ventilated pediatric patients who became colonized with *Burkholderia*due to the use of contaminated tap water for oral and tracheostomy care. New cases stopped once use of tap water for oral and tracheostomy care was stopped.59Another report includes 66 patients in Toronto who acquired an extended-spectrum β-lactamase-producing *K. oxytoca*; multiple hand-washing sinks were found to be positive with the outbreak strain. After a change in sink drain design, revised strainers to reduce backsplash, and replacement of sink traps, cases were no longer noted.60Of particular concern is a recent report from Australia of a carbapenem-resistant Enterobacteriaceae (CRE) outbreak associated with contaminated sinks. Ten ICU patients were found positive for Enterobacteriaceae; of these, four were *S. marcescens*isolates that matched isolates from environmental sink cultures. Again, as with the Hota report,34sink design contributed to environmental contamination. Sinks were small and shallow, with a tap that directed water over the drain.61These ongoing reports illustrate the value IPs bring during the ICRA process to ensure that hand hygiene is convenient and accessible but that the fixture does not contaminate the surrounding environment with water droplets.

Faucets in "clinical" or flush ("flushing rim") sinks located in utility rooms in which aerators have been removed may benefit from installation of splashguards. These provide protection to staff and nearby equipment and environmental surfaces. Toilets have been studied for aerosol production but have not been implicated in direct disease transmission.36However, although toilets have not been implicated in direct disease transmission, vacuum toilet designs may contribute to less environmental contamination from mist and splash created during flushing rather than gravity toilet designs.

Stationary and Portable Eyewash/Drench Shower Stations

Eyewash/shower stations may go unused for months and pose a possibility of contamination; water-associated microorganisms (e.g., *Acanthamoeba*) have been reported to contaminate these

stations.1Rutala and Weber5surveyed 40 eyewash stations and found contamination primarily with *Pseudomonas*,62*Legionella*spp., amoebae, and fungi. Following the report of *Acanthamoeba*contamination, the Occupational Safety and Health Administration (OSHA) issued a bulletin recommending cleaning and disinfection methods.48OSHA recommended a schedule for flushing that follows American National Standards Institute (ANSI) recommendations for flushing the system for a 3-minute period each week.63

Ice Storage Chests and Ice Machines

Contaminated ice and ice machines have been implicated as sources of infection, though such reports are not common. In one instance, a cryptosporidiosis outbreak was traced to an ice machine, and the source of contamination was an incontinent individual who was handling the ice.64True and pseudo-outbreaks from atypical mycobacteria contamination (e.g., *M. gordonae*) have been linked to ice machines.65,66One report also implicated aspiration of ice contaminated with *Legionella*spp. in a patient with a swallowing disorder.43

Water Baths and Related Devices

Water baths and related devices are used to warm blood or blood products (e.g., cryoprecipitate, fresh frozen plasma) and other liquids, such as intravenous solutions or peritoneal dialysate. Such baths can become contaminated with pathogenic organisms, such as *P. aeruginosa*and *Acinetobacter*, and several outbreaks or case reports possibly associated with these types of reservoirs have been identified.1,67To avoid contamination, manufacturer recommendations should be followed (e.g., perform leak tests), and policies for routine cleaning and disinfection should be considered. The use of impermeable plastic overwraps to keep surfaces of blood products dry and free of potential contamination is another protective measure. New warming technologies that avoid water baths (i.e., waterless systems) have been developed, and such products eliminate a potential water source for contamination.

WHIRLPOOL/SPALIKE BATHS

Pools, whirlpools, hot tubs, and physiotherapy tanks are used in both inpatient and outpatient settings. Specific types of spalike tubs are used in labor and delivery as "birthing tanks." Microbial contamination may involve the drains and agitators and result in cross-contamination between patients if there is inadequate cleaning and disinfection of the plumbing and drains. Skin infections related to water immersion have been recognized for many years and have been reviewed extensively by Rutala and Weber.5*P. aeruginosa*has been associated with hot tubs and whirlpools; burn patients are uniquely susceptible to infection, and prevention of contamination in this type of equipment has been studied extensively.68,69.

Patient Care Equipment

Equipment that is rinsed in tap water can serve as sources of infection. For example, medication nebulizers rinsed in tap water were suspected as the source of an outbreak of legionellosis in a community hospital.70Gram-negative organisms can multiply to substantial concentrations under the right conditions, as noted in numerous outbreaks related to endoscopes and automatic endoscope reprocessors (AERs). For a full discussion of AER see **55. Endoscopy**and the CDC-EIC recommendations on water quality for miscellaneous medical equipment connected to water systems (e.g., AER and dental equipment).1Meyers and colleagues16also describe an outbreak of infections following liposuction that was associated with rinsing of instruments with tap water.

Toxic anterior segment syndrome (TASS) has also focused attention on reprocessing and sterilization of surgical instruments used for cataract surgery. Waterborne microorganisms likely resulted in intrinsic

contamination of a balanced salt solution used for this procedure and resulted in a multistate outbreak of TASS.71These investigations and others have stimulated publication of new recommendations to prevent TASS.72

Prevention Strategies

Strategies to prevent infections associated with water depend on optimal design, appropriate preventive maintenance, risk assessment, and surveillance for HAIs that includes a high index of suspicion for infectious agents associated with moisture and water distribution systems. Importantly, identification of cases of legionellosis among the population served may reveal that the source of the pathogen is completely external to the facility where cases are identified.73For details on surveillance of HAIs, see **11. Surveillance**.

RISK ASSESSMENT

IPs routinely perform risk assessments to identify vulnerabilities, determine actions to take if indicated, and develop a plan to monitor and plan for emergencies. An example of this is ICRA process used during design and construction (see) that looks at the population to be served (or the type of service to be performed, such as a laboratory or pharmacy) in an area to be constructed and considers optimal design features and construction recommendations aimed to prevent infections.

An emerging model under proposal for assessing water risk is to develop a hazard analysis and critical control point (HACCP) plan. The HACCP process has been in use since the 1960s within the food industry to evaluate risks associated with food processing and is now being considered as an approach to evaluate water safety in multioccupant buildings such as hospitals. This process includes characterizing the waterborne pathogen infection risk associated with a building and its occupants. For buildings that meet established risk criteria, it is necessary to assemble a team to do the following:

1.Describe how water is processed for the building and used within the building, and schematically represent in a flow diagram.

2.Identify potential hazards for each step in the process.

3.Determine if the hazard is significant for each step of the process (yes/no).

4.If YES, determine the hazard control being applied or that could be applied at that step. Each step at which hazard control is applied is a "critical control point."

5.For every critical control point, determine:

a.The critical control limit

b.The monitoring method

c.The frequency of monitoring

d.Corrective actions if limit is violated

6.Verify that the overall HACCP plan is being implemented.

7.Validate plan effectiveness by providing evidence.

IPs and facility managers must work together to establish a process for assessing the risk for waterborne pathogen transmission within the HCF; surveillance data is an essential component of this assessment. Risk assessment will help guide design decisions during construction and help determine the effectiveness of maintenance activities within the facility.

WATER DISTRIBUTION SYSTEM DESIGN

Standards and Recommendations

Prevention and interventions rely primarily on good design and maintenance. As noted, the guiding principle to prevention is removal and elimination of water reservoirs.

Decorative Water Fountains, Water Walls

If features such as decorative water fountains or water walls are currently installed anywhere within or outside of HCFs, organizations must ensure systematic disinfection and preventive maintenance.1Legionellosis has been associated with decorative water features in numerous settings, including both indoor and outdoor features,53–57supporting the need for effective design and routine disinfection and maintenance.5

Potable Water Supply System

As noted in **114. Heating, Ventilation, and Air Conditioning**; ; and the 2010 Facility Guidelines Institute (FGI) Guidelines for Design and Construction of Health Care Facilities2are sources of design guidance for infection prevention. Examples of important design specifications are highlighted below. For example, water delivery systems should be designed to supply water at sufficient pressure to operate all fixtures and equipment during maximum demand. Provision of two separate water lines from a looped municipal water supply system to a facility would minimize interruption of water service. General guidelines include:

• Water-service mains, branch mains, and other main waterlines should have stop (isolation) valves for each fixture. Valves isolate a portion of the water system from the remainder of the system when repair is required.

• Vacuum breakers should be installed on faucets. Approved backflow preventers (i.e., antisiphon devices) protect water supply systems from contamination in high-risk areas such as dialysis units. (See **39. Dialysis**for microbiologic monitoring, as recommended by the Association for the Advancement of Medical Instrumentation [AAMI].)

• Floor drains should be avoided as much as possible and specifically should not be in operating or delivery rooms, with the exception of dedicated cystoscopic rooms.

• Drainage piping should not be installed in ceilings or exposed in operating and delivery rooms, nurseries, or other sensitive areas. If overhead drain piping is unavoidable, provisions must be made to protect the space below from leaks, condensation, and dust particles.

• Water supply pipes with dead ends should be avoided or, if found, should be minimized.

Temperature Specifications

A water heating system should have sufficient supply capacity at the temperatures and amounts specified in Table 115-2 for hospitals (see equivalent Table 2.1-5, 2010 Guidelines2). The temperature is measured at the point of use or inlet to the equipment. Hot water tank temperatures may be set higher. Hot water distribution systems serving patient care areas should use constant recirculation to provide

continuous hot water at each outlet. In nursing facilities, the water system should be designed appropriately to supply hot water to meet the demands of resident care. The water temperature for showers and bathing should be appropriate for comfortable use, and the 2010 Guidelines permit a temperature range between 105°F (41°C) and 120°F (49°C). The guidelines seek to balance potential risks of scalding against the risks of exposure to *Legionella,*because the older standard (110°F [43°C]) is near the temperature supporting growth of *Legionella*(77°F to 108°F [25°C to 42.2°C]).58,74,75The CDC recommends maintaining water temperatures at 124°F (51°C) or higher and cold water temperatures at 68°F (20°C) to control *Legionella*; again, however, concerns with scalding move many building codes to limit hot water temperature to 120°F (as with the FGI Guidelines). Mixing pressure valves must then be used to control water temperature at the use outlet so that the water system can be maintained at the higher temperature without risk of scalding.1,58Such decisions are important safety and cost/benefit issues and are determined state by state.76(See **84. Legionella pneumophila**.)

Table 115-2 Hot Water Use—General Hospital

	Hot Water Use		
	Clinical	Dietary	Laundry
Liters per sec per bed1	11.9	7.2	7.6
Gallons per hour per bed1	3	2	2
Temperature (°C)	41–492	493	714
Temperature (°F)	105–1202	1203	1604

1Quantities indicated for design demand of hot water are for general reference minimums and shall not substitute for accepted engineering design procedures using actual number and types of fixtures to be installed. Design will also be affected by temperature of cold water used for mixing, length of run, and insulation relative to heat loss, etc. As an example, total quantity of hot water needed will be less when temperature available at the outlet is very nearly that of the source tank, and the cold water used for tempering is relatively warm.

2The range represents the maximum and minimum allowable temperature.

3Provisions shall be made to provide 180°F (82°C) rinse water at ware-washer (may be by separate booster).

4Provision shall be made to provide 160°F (71°C) hot water at the laundry equipment when needed. (This may be steam jet or separate booster heater.) However, it is emphasized that this does not imply that all water used would be at this temperature. Water temperatures required for acceptable laundry results vary according to type of cycle, time of operation, formula of soap and bleach, and type and degree of soil. Lower temperatures may be adequate for most procedures in many facilities but the higher temperature 160°F (71°C) should be available when needed for special conditions.

From Facility Guidelines Institute. 2010 Guidelines for Design and Construction of Health Care Facilities. Chicago: The American Society for Healthcare Engineering (ASHE), 2010: Table 2.1–5, pp 87.

Other factors (dynamic versus static flow, type of water heating system, and water treatment) have varying effects on the system's ability to control microbial growth at the design temperatures. For example, preliminary reports suggest that use of chloramines, rather than chlorine, may reduce the risk

of *Legionella*in the distribution systems of municipal water supplies.1,28Multiple reports support the reduced risk of hospital-associated Legionnaire's disease when municipal water treatment plants used monochloramine.77,78Monochloramine applications for facility use are under development but are not yet available as practical options. Chlorine dioxide, another application useful in cold water and able to penetrate pipe biofilms, has been evaluated in some institutions and used for infection prevention with some success in other countries.79–82A 17-month evaluation in a U.S. hospital using chlorine dioxide demonstrated its efficacy and safety in maintaining appropriate levels of chlorine dioxide and chlorites.82,83Other treatments with the potential to prevent or eradicate *Legionella*have been reported, such as copper-silver ion treatment, which also penetrates the biofilm and avoids pipe corrosion associated with hyperchlorination.41,42,51,52,84,85A published review summarizes the experiences of the first 16 hospitals to install copper-silver ionization systems for *Legionella*disinfection, covering use periods of 5 to 11 years, with a high degree of success.86Ultraviolet light is another modality that is successful with in vitro bacteriocidal effects but cannot effectively penetrate the biofilm of a contaminated water system. However, it can prevent contamination and may be used with other disinfection modalities.87,88

If a risk assessment is performed and it is determined that a supplemental disinfection method is indicated, Table 115-3 can provide information that may help guide appropriate selection of a water disinfection method by comparing different methods.

Table 115-3 Comparison of Water Disinfection Methods in a Hospital Environment

ITEM	DISINFECTION SYSTEM

Any intervention that reduces the corrosion or potential for dislodgment and aerosolization of contaminants to patients or building occupants is key to overall prevention. To routinely prevent waterborne microbial contamination, the CDC currently recommends that organizations unable to attain the recommended temperatures or install thermostatic mixing valves follow a protocol to periodically increase the water temperature up to 150°F (up to 66°C) or chlorinate the water and flush it through the system.1

Other temperature specifications from the 2010 Guidelines concern provisions to supply 160°F (71°C) water for laundry purposes when a facility supports an onsite laundry service. Footnotes for Table 115-2 (2010 FGI Guidelines, Table 2.1-5) state that water temperature needs for laundry services will vary according to wash cycle, time of operation, formula of soap and bleach, and type and degree of soil. Significant reductions of microbial contamination can be achieved at lower temperatures, with concomitant major savings (see **111. Healthcare Textile Services**).

EQUIPMENT DESIGN ISSUES

Hand-washing Stations

The major engineering and infection prevention method for reducing infection transmission is adequate and proper placement of hand-washing stations. The 2010 Guidelines define a hand-washing station as "an area providing a sink with hot and cold water supply and a faucet that facilitates easy on/off mixing capabilities. The station includes provision of cleansing agents and drying capability."2The guidelines require a hand-washing station in each patient room, outside the patient's cubicle curtain, and in the toilet room. Access for use is essential to prevent the spread of infection, and improper placement and maintenance can add to the environmental reservoir of contaminants. As discussed, design of the hand-washing sink and assessment after installation for unwanted dissemination of water droplets are important aspects to address.34If existing space (in major renovation) does not permit a sink in the patient room, state health authorities may provide a waiver and permit instead a "hand sanitation station" that is "a dispensing location for a waterless, antiseptic hand rub product that is applied to reduce the number of microorganism present on the hands."2

Functional consideration and placement of dispensers of waterless alcohol-based hand rub (ABHR) is strongly encouraged and endorsed by both CDC Guidelines and patient safety goals from accreditation agencies.89,90However, the 2014 Guidelines do not consider dispensers of ABHR as equivalent to hand-washing sinks, as CDC Guidelines prescribe the need to use soap and water for washing hands contaminated with visible proteinaceous material.2,89

ABHR use is a centerpiece of strategies to improve hand hygiene by HCP, and placement of ABHR in patient care areas should include input from direct care providers. Following a national stakeholder meeting regarding ABHRs and fire safety in HCFs held in July 2003, and cohosted by the CDC and the American Hospital Association (AHA), a major campaign was initiated by these organizations to encourage the installation of dispensers just inside patient rooms, treatment rooms, suites, and other acceptable areas. Results of a fire modeling risk study indicated that 1.2 L dispensers of ABHR solution could be installed safely in corridors under certain conditions, but the then existing (2003) fire codes prohibited such placement. Key codes have been modified, but design considerations remain important for ease of access as well as maintenance for functionality and safety.91Fire code issues continue to be a challenge and can be monitored from several sources. (In Supplemental Resources, see American Society for Healthcare Engineering and Premier Safety Institute.)

The use of automated hand-washing machines has not yet clearly improved long-term compliance with hand washing, though design efforts continue.89,92,93

Design Considerations for Hand-washing Facilities

• Faucets: Careful investigation into hand-washing equipment design (types of faucets) may further reduce hand contamination. Nontouch faucet fittings have increased in usage and may require extra attention to maintain temperature and pressure and may require frequent usage to avoid water contamination. Electronic-eye faucets have been the focus of study for increased correlation with *Legionella*contamination; a risk assessment is recommended to determine if their use is optimal in various settings.94–98

• Location: Sinks need to be placed in convenient and accessible areas but should be positioned to prevent splashing of nearby equipment and supplies.34,99Surfaces adjacent to water fixtures should be nonporous to resist fungal growth.47Areas beneath sinks should not be used for storage because of proximity to sanitary sewer connections and risks of condensation, leaks, or water damage. Accrediting and regulatory agencies discourage or cite this practice under general sanitation standards to ensure that clean materials are not at risk of contamination. Splashguards for clinical or flushing rim sinks should be considered for protection of HCP, as already noted.

• Soap: Built-in refillable soap dispensers should be avoided to reduce the need for cleaning and to prevent contamination problems.1,89Washable dispensers with disposable cassettes are effective in reducing contamination risks, and maintenance is far less labor intensive.

• Drying: Sufficient space should be provided for paper towel dispensers, soap, and waste disposal. Paper towel dispensers should be designed to protect against soil or dust and to provide for single-unit dispensing. Ideal designs dispense the towel without direct hand contact with the dispenser. If hot-air dryers are used, installation should preclude possible contamination by recirculation of air. Research on hand contamination during drying suggests the importance of evaluating different methods and designs, as well as the site and placement of towel dispensers.100–103

• Aerators: As noted, aerator usage is not recommended, though CDC guidelines indicate that removal is an unresolved issue for immunocompetent patients.1Proper sink design (i.e., depth of the sink, length of the spout, distance between the spout and sink drain) may reduce or eliminate the hazard. Regular cleaning also will reduce risks if aerators are used.30,58Some building codes do not allow aerators but will allow nonaerating, laminar flow control devices, which slow down the flow of water. Many manufacturers locate this type of control device at the base of the faucet, so it will not be visible at the outlet.

• Sink controls: Depending on local codes, faucets can be operated by hand; by elbow-, knee-, or foot-operated controls; or automatically by electronic or other sensor-driven controls (example: California code only allows "no touch" or wrist-blade controls on any acute healthcare fixture intended for hand washing). Other hand-washing machines being tested may have merit, but efficacy is not yet well described. Foot- and knee-operated and infrared sensor controls may be more expensive but are required in areas where the risk of touch contamination should be eliminated (e.g., scrub sinks for invasive procedure rooms). Blade handles on clinical sinks should be at least 6 inches long for operation without hands (i.e., elbow operated). In general patient care areas, hand-operated fixtures for routine hand washing may use single-lever or wrist-blade devices.2Electronic controls offer the advantages of no-touch operation and save water. Some disadvantages include the inability to adjust water temperature; most use mixing valves that deliver tepid or warm water only; most will be on emergency power but, if battery-powered, most are designed to have a visual indicator (e.g., flashing light) long before battery expiration. Some studies have found that the concentration of microorganisms is higher in fixtures with electronic control; however, there is no definitive evidence this increases infection risk for patients in areas where these are installed.94–98Fixture design and location may therefore be of more importance.

Newer designs are also offering automatic flushing capability to reduce stagnation of water in locations where sinks may not be used frequently; this may help reduce risk of biofilm formation, but this is not definitively known, nor is there any published evidence of clinical reduction in infection associated with these designs.

Whirlpool/Spa Bathing Facilities

Whirlpools, tubs, and spalike bathing facilities all require attention to design and maintenance to reduce risks of cross-contamination. Physical therapy tubs or Hubbard tanks commonly are used in facilities that need to provide a range of treatments. As noted, various types of bathing facilities have become available for mothers in birthing rooms, and though these facilities are similar to physical therapy units, they are somewhat different in design (see **41. Neonates**and **66. Rehabilitation Services**.) Procedures for use and disinfection should be consistent with the American Physical Therapy Association recommendations for tanks and equipment. The CDC-EIC guidelines provide a full description of the issues.1

Plumbing for spa baths or spalike tubs has longer piping than that for typical whirlpools. Thus, contaminated water may become trapped after apparent draining and could be flushed into the tub during the next use. Another example of a design problem contributing to contamination is the location of the whirlpool drain. During an outbreak investigation, it was determined that the drain of the whirlpool bathtub, contaminated with the epidemic strain, closed approximately 2.54 cm below the drain's strainer. Water from the faucet, which was not contaminated, was contaminated with *P. aeruginosa*from the drain when the tub was filled. The design of the drain allowed the epidemic strain to be transmitted to immunocompromised patients using the whirlpool bathtub. The authors suggest that use of whirlpool bathtubs with drains that seal at the top could eliminate this potential source of infection.68When considering installation of such tubs, it is essential to communicate with state regulators and others with design expertise. Cleaning and disinfecting the tub and jets with specific spa cleaning products and proper draining and flushing sequences are essential when considering their use.104Pipeless spa baths are now available commercially for use in HCFs as well as homes and may reduce these concerns considerably (see Supplemental Resources).

Two reported outbreaks of dermatitis and other infections associated with *P. aeruginosa*in swimming pools and hot tubs prompted the CDC to issue disinfection recommendations in late 2000 for facility

operators.105Although these outbreaks occurred in hotels, the guidelines fit other institutional settings. The report noted that the use of cyanurate reduces chlorine loss from ultraviolet light exposure but also reduces the antimicrobial activity of chlorine.

To reduce the risk of *Pseudomonas*dermatitis and other infections from waterborne organisms, the CDC recommends that pool and hot tub operators adhere to the following105:

• Follow pool and hot tub recommendations and regulatory requirements for pH and disinfectant levels.

• Have a thorough knowledge of pool and hot tub operation.

• Provide training for staff members on the capabilities, maintenance, and emergency-alert procedures of remote monitoring systems.

• Closely monitor pool and hot tub chlorine levels during periods of heavy use.

• Recognize that hot tub temperatures cause chlorine to dissipate rapidly.

• Understand the appropriate use and effects of cyanurates on disinfection and testing.

Cooling Tower Design

The 2004 CDC guidelines for preventing healthcare-associated pneumonia briefly address design issues related to new cooling towers for preventing the spread of *Legionella*. The 2003 CDC-EIC guidelines reinforce older recommendations that new cooling towers should be designed to direct tower drift away from the hospital air-intake system, minimizing aerosol drift; drift eliminators should be installed, and effective EPA-approved biocides should be used regularly for operational cooling towers.1,35Practical recommendations for design and maintenance of cooling towers may be located from engineering resources.106,107(See Supplemental Resources.)

Design Issues for Disposal of Human Waste

There is no safe, aesthetic management of stool and other human waste in bedpans; system design should provide for emptying bedpans without leaving the patient room or for minimal travel distance to clinical/flushing rim sinks in treatment areas. Management of fecal waste during disasters that involve extensive power loss and subsequent loss of water or sewer is critical (see **119. Emergency Management**). This process is especially challenging when caring for critically ill patients. One option is to equip all patient rooms with attached bathrooms; another is installing utility rooms with clinical or flushing rim sinks between patient rooms. In ICUs this consumes precious square footage that could be dedicated to other uses, because most patients needing this care are not ambulatory. Barker and Jones,108using an in vitro study of dispersal of *Serratia marcescens*and a bacteriophage during flushing of a toilet fixture, demonstrated significant release of these microorganisms over short ranges and consequent contamination of the fixture. Their observations indicate that careful attention is needed regarding proximity of any toilet fixture to the immediate area around the patient. Swivette toilets that can be recessed back under a cabinet have been used in some ICUs. However, in-use experience with these has been mixed, and they are no longer included within the FGI Guidelines. The plumbing connections may leak, the low height of the fixture may make it hard to use by personnel and impractical for patients, and contamination of adjacent surfaces is possible. Patients who need critical care but have less intense acuity levels may be able to ambulate. FGI 2010 Guidelines support at minimum a toilet room or a clinical sink between two patient rooms, whether medical, coronary, or pediatric ICUs.

PREVENTIVE MAINTENANCE

Potable Water Distribution Systems, Cooling Towers, and Environmental Surfaces

Preventive maintenance for potable water systems includes a number of issues (e.g., cleaning and disinfection of cooling towers and water fountains).

Among the most critical prevention methods is maintenance of appropriate water temperatures. The American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) recommends that cold water be stored below 68°F (20°C) and hot water above 140°F (60°C), circulating with a minimum return temperature of 124°F (51°C) or the highest allowable temperature specified in state regulations and building codes.106If the temperature setting of 124°F (51°C) is permitted, installation of preset thermostatic mixing valves reduces risk of scalding (as previously discussed) and is recommended by the CDC.1To address safety concerns, the 2006 Guidelines have defined a temperature range rather than a maximum for hot water temperatures for clinical use; that is, 105°F to 120°F (41°C to 49°C).2

Dead legs (capped piping with no flow) should be removed or avoided. Biocides should be applied at label dosages to control growth of other bacteria, algae, and protozoa. Removal or prevention of sediment accumulation also may reduce other niches that may amplify microbial growth. Plumbing that includes self-draining shower lines, antiscald valves, and pipe insulation may reduce contamination risks. Routine sampling is not encouraged except for tracing studies or outbreak investigations.1More emphasis is placed on clean equipment in excellent state of repair.94Hot and cold water systems should be inspected and cleaned as defined by the facility's operational and preventive maintenance schedule. Finally, filters for outside air must be kept dry because wet filters are ineffective; filters must be cleaned and replaced with a frequency directed by the manufacturer.

Dead legs caused by normally closed valves on equipment bypasses or infrequently used lines should be provided with drain valves.

Eyewash/Shower Stations

ANSI recommends flushing eyewash stations weekly for 3 minutes.63

Water Baths and Related Devices

If water baths and related devices are used to warm fluids, such as blood products or peritoneal dialysate, policies for routine cleaning, disinfection, and changing of the water should be in place. After cleaning, the bath/device should be filled with water to which a germicide has been added. Manufacturer recommendations should be followed (e.g., perform leak tests); wrapping blood products in impermeable plastic would also keep them dry and free of contamination.5,67

Ice Storage Chests and Ice-Making Machines

The CDC developed an advisory in reference to sanitary care and maintenance of ice storage chests in 1968 in response to a hospital outbreak traced to the use of contaminated ice. This advisory was published again in 1998 because of continuing requests and inquiries related to this subject.1,66The 2003 CDC-EIC guidelines support this advisory and recommend first checking for available instructions from the manufacturer and determining whether EPA-approved disinfectants are suitable for the equipment. If none is available, a general regimen is suggested, based on the advisory. The following procedures should be followed to reduce the likelihood of contamination of ice storage chests and ice-making machines in HCFs1,66:

Weekly–Monthly

• Clean ice storage chests on a preset schedule. Weekly to monthly cleaning of open chests is suggested; less frequent cleaning may be possible with ice-making machines.

• Cleaning should be done with fresh soap or detergent solution after disconnecting the unit, removing and discarding all ice, and allowing the ice storage chest to warm to room temperature. Use clean materials to scrub all surfaces, paying particular attention to door tracks, guides, and gaskets.

• After cleaning, rinse all surfaces of the chest with fresh tap water, wipe dry with clean materials, rinse again with a 10- to 100-ppm chlorine solution (1 to 8 mL of sodium hypochlorite [household bleach] per gallon of water), and allow all surfaces to dry before returning the unit to service.

Monthly–Quarterly

• On a regular schedule, perhaps monthly to quarterly, disconnect ice-making machines, discard all ice, and disassemble removable parts of the machine that come in contact with the water used to make ice. Thoroughly clean the machine and its parts with detergent and water.

• Check for the need of possible repair of any portion of the machine, replacing feeder lines as needed. Ensure the presence of an air space in the tubing that leads from the potable water inlet into the water distribution system of the ice making machine. Inspect for insect or rodent infestation under the unit and treat if necessary. Check the gasket around the door of the ice storage chest (open-compartment models) for cleanliness and evidence of possible leakage or dripping of contaminants into the chest. Clean the chest as described with detergent and water.

• Circulate a 50- to 100-ppm chlorine solution throughout the entire storage and ice making system of the machine according to the manufacturer's recommended cleaning and sanitizing procedures. Let the 50-ppm chlorine solution remain in the ice-making and storage system of the machine for 4 hours (or at least 2 hours for a 100-ppm chlorine solution).

• Remove the chlorine solution, flush the system with fresh tap water, allow the ice storage chest to dry, and then return the unit to service.

Whirlpools, Spas, and Tanks

Hydrotherapy pools and immersion tanks present unique disinfection problems. Facilities with large hydrotherapy pools containing thousands of gallons of water cannot drain the pools after each patient use; such pools are generally drained and cleaned every 1 to 2 weeks. CDC guidelines recommend installation of a water filter of sufficient size to filter all the water at least three times per day and to chlorinate the water so that a free chlorine residual of approximately 0.5 mg/L is maintained at a pH of 7.2 to 7.6. Local public health authorities can provide consultation regarding chlorination, alternate halogen disinfectants, and hydrotherapy pool sanitation. Hubbard and immersion tanks are drained after each patient use. The CDC recommends cleaning inside surfaces with a disinfectant-detergent, then rinsing with tap water. After the last patient each day, an additional disinfection step should be performed; this involves circulating a chlorine solution (200 to 300 mg/L) through the agitator of the tank for 15 minutes and then rinsing. It also is recommended that the tank be thoroughly cleaned with a disinfectant-detergent, rinsed, wiped dry with clean cloths, and not filled until ready for use.1

An alternative approach to control of contamination in hydrotherapy tanks frequently used in burn units is the use of plastic liners to create a "whirlpool effect" without agitators. Such liners make it possible to minimize contact of contaminated water with the interior surface of the tank and obviate the need for agitators that may be difficult to clean and decontaminate.

If piped spa-style tubs are used, the tub and jets should be cleaned and disinfected with specific spa-cleaning products, and proper draining and flushing sequences should be used. Equipment may be stainless steel, plexiglass, or tile, but it remains critical to consult with manufacturers to identify appropriate cleaning products for their surfaces. Spa baths were originally designed for residential use, but as noted, there are better designs now available for healthcare with improved surfaces and cleanability.

Patient Care Equipment

Concerns for contamination of respiratory therapy equipment (e.g., humidifiers, nebulizers), bronchoscopes, and other patient care equipment involving water and moisture require constant vigilance. Gram-negative organisms can multiply to substantial concentrations under the right conditions. Sterile water should be used, instead of tap water, for rinsing semicritical equipment and devices used on the respiratory tract after they have been chemically disinfected.35Reported outbreaks have once again drawn attention to both design and disinfection issues of automatic endoscopic machines, as well as endoscope design.109,110Recommendations for complete air drying or rinsing with alcohol before storage were discussed in a joint bulletin issued by the CDC and the U.S. Food and Drug Administration (FDA).111(See **55. Endoscopy**.)

REMEDIATION STRATEGIES

Planning hazard prevention through system and equipment design as well as preventive maintenance remain the strongest approaches to strategies. However, given the best of intentions, disruptions do occur whether during construction, natural disasters, or technical or manmade disasters. Remediation approaches are discussed in terms of utilities, water leaks/flooding, and controlling *Legionella*contamination if problems occur.

Utility Disruptions

Emergency preparedness requires a number of strategies, including sufficient storage of supplies and follow-up response protocols for planned or unplanned power loss affecting water flow. Without planning and rapid response, power outages and water service interruptions can lead to major problems. IPs should participate in planning and response to prevent, detect, and/or reduce infectious hazards, in accordance with TJC utility management and emergency management standards.112

Facility policies should include contingency planning for supplying water for drinking, cleaning, bathing, and toilet flushing. In addition, an unplanned disruption may affect the water distribution lines and require heating or chlorination, flushing, and water testing before resumption of use. CDC guidelines offer specific guidance on remediation strategies for the water distribution system, including conditions involving a "boiled water advisory" (BWA).1,2,42IPs should be aware and have access to their facility's water-quality analysis report, which must be provided to local water control authority under the auspices of the EPA. The report includes elements measured against standards such as turbidity (1 unit), microbiologic contaminants (0 coliform bacterium/100 mL), and residual disinfectant levels, such as chlorine (less than 4 mg/L chlorine).113A major component of contingency planning is identifying the preferred method of decontaminating the hot water system after a disruption. If there is a separate water storage and treatment system for dialysis, this should be included in the plan, including filter changes and disinfection.1(See **31. Cleaning, Disinfection, and Sterilization**; **39. Dialysis**; and **119. Emergency Management**.)

Other practical considerations in planning for an infection prevention policy for water service disruptions involving a BWA are listed below; communication plans for each are critical:

• Operational: Pre-established agreement and rapid delivery in an emergency with commercial suppliers of bottled water should be in place and should consider at least a 24-hour supply. Risk assessments should include whether or not the facility has a facility-based reservoir such as a water tower or well as a backup resource, or water treatment systems to generate water for dialysis.

• Water for consumption (ice, oral hygiene, food sanitation): Boil water to rolling boil for at least 5 minutes and allow to cool for 10 to 15 minutes, or use bottled water. Posting of warning signs should include water fountains and ice machines. After the BWA is lifted, specific protocols for flushing and cleaning water fountains and ice machines are included in CDC guidelines, as noted.1

• Hand hygiene: Identify waterless products (gels, alcohol, packets, or wipes) to have on hand for hand washing; identify specific products that are safe and easy to use (i.e., distinguish hand-washing products from environmental cleaning products).

• Skin and wound care: Surgical incisions reseal within 24 to 48 hours after closure, and water available under a BWA including bottled water would be acceptable. However, sterile water should be used for irrigation of wounds or incision.

• Bathing and showering: Identify products (such as bottled water and no-rinse cleansing cloths) to have on hand for patient use (infants/adults); consider requesting personnel to bring bottled water for themselves to conserve supplies for patient use.

• Cleaning, disinfection, and sterilization: Because surgical instruments are sterilized after cleaning and packaging for reprocessing, any microbes present in water under a BWA will be inactivated. No additional precautions are therefore necessary for these instruments after they have undergone a proper sterilization process. Routine practices for reprocessing endoscopes with narrow internal channels, such as forced air drying and flushing internal lumens with alcohol, will mitigate any contamination from rinse water even during a BWA.

• Environmental cleaning: Identify products for environmental cleaning and wiping during the water disruption. The facility should carry out a risk assessment for water used to dilute surface disinfectants if premixed, ready-to-use disinfectant or impregnated disposable cloths are not available.

• Waste: Determine whether toilets can be flushed; if flushing is possible but water is shut off, identify locations where water may be stored and locate buckets that may be used for flushing.

• Determine the communication process to implement before use of taps and other equipment can resume.

• During the water restoration process, expect dislodging of scale with potential to adversely affect valves (e.g., toilet) that may malfunction and require disassembly with cleaning or replacement; spare parts should be on hand.

• Be prepared to clean up particulates that may be sprayed into sinks, tubs, and showers as water is restored and air pressure is purged from the pipes.

• Consider keeping restroom doors closed in high-risk patient areas until water restoration processes and cleaning of the fixtures are complete.

Flooding and Water Leakage

Water seepage and retained moisture may lead to serious bacterial and fungal contamination in the air-handling systems.46,47Practical suggestions for cleanup and treatment of wet surfaces, whether

ceilings, walls, or flooring, are available.1,114Cleanup protocols affecting various surfaces and furnishings are discussed in **107. Environmental Services**. The key to preventing infection problems consists of removal of the moisture source, cleanup within 24 to 48 hours, disinfecting with diluted bleach solutions, and thorough drying.1,114,115

Controlling Legionella

One of the major concerns for potable water contamination in HCFs is the prevention of *Legionella*, particularly following water disruptions. However, the mere presence of *Legionella*organisms in a water system does not predict the occurrence of disease outcomes. Determination of a dose-response relationship has been sought in several studies but has not yet been identified.50Likewise, studies of the efficacy of routine microbiologic sampling of potable water in HCFs has provided mixed results, so the 2003 CDC-EIC Guidelines remain a logical guide to a facility-based prevention program.116,117

Several documents outline control strategies for legionellosis. These include the 2003 CDC-EIC and 2004 Pneumonia guidelines, OSHA's technical manual, the ASHRAE Guideline, and the Cooling Technology Institute Guidelines.1,35,74,106,107At this writing there are also recommendations open for public comment from ASHRAE for *Legionella*risk assessment using the HACCP approach. The CDC-EIC guidelines recommend control measures for all facilities and add additional recommendations for facilities with immunosuppressed patients or transplant units (e.g., for hematopoietic stem cell transplants [HSCT] and solid organs). CDC guidelines and OSHA's technical manual provide recommendations for follow-up procedures when problems have been identified.1,74The CDC-EIC guidelines provide an extensive review of multiple approaches.1

CDC Guidelines: Legionellosis Prevention and Response

There are similar steps that should be undertaken when either a single case of laboratory-confirmed nosocomial Legionnaire's disease is identified or two or more cases of laboratory-confirmed disease, which might be healthcare-associated, occur within 6 months of each other (see the CDC-EIC guidelines for further discussion). A brief summary of steps follows1,35:

• Inform and consult with local public health authorities.

• Conduct an epidemiologic investigation via retrospective reviews of microbiologic, serologic, and postmortem data to identify previous cases. In addition, intensive prospective surveillance should be established to identify additional cases. Surveillance should be continued for at least 2 months, even if no further cases are identified.

• If there is evidence of ongoing transmission, an environmental investigation (culturing water samples) should be conducted to help determine the source.

• If a source is identified, decontamination measures should be instituted.

• If *Legionella*is detected in one culture (e.g., conducted at 2-week intervals during 3 months), control measures should be reassessed, modified as needed, and decontamination repeated.

• The CDC makes no recommendation for routine culturing of the water system in hospitals without HSCT or solid-organ transplant programs.

• If a case is identified in a severely immunocompromised patient or if the hospital houses severely immunocompromised patients in HSCT or solid-organ transplant programs, an environmental investigation should be initiated in addition to the epidemiologic investigation. Hospitals that do not

house severely immunocompromised patients do not need to conduct an environmental investigation initially. However, if transmission is shown to be ongoing in such facilities, an environmental investigation is warranted.

• Environmental investigations involve collecting water samples from potential sources of aerosolized water, as outlined in CDC Guidelines appendices. If a source is identified, it should be immediately decontaminated. If a source is not identified, surveillance should be continued for at least 2 months and, depending on the scope of the outbreak, decontamination of the hospital's water distribution system should be undertaken or deferred pending identification of the source of *Legionella*organisms.

• If the source is a heated water system, the following decontamination steps are suggested:

oSuperheat (flush each distal outlet of the system for at least 5 minutes with water 160°F to 170°F [71°C–77°C]) or hyperchlorinate (flush all outlets of the system for at least 5 minutes with water containing 2 mg/L [2 ppm] free residual chlorine). Post warning signs at each outlet that is being flushed to prevent scald injury or excessive chlorine exposure to patients, staff, or visitors.

oDepending on local and state regulations regarding potable water temperature in public buildings, maintain potable water at or above the temperatures recommended earlier (less than 124°F [less than 51°C]); cold water (less than 68°F [less than 20°C]) or chlorinate heated water to achieve 1 to 2 mg/L free residual chlorine at the tap. Clean hot water storage tanks and water heaters to remove accumulated scale and sediment.

oRestrict immunosuppressed patients from taking showers and use only sterile water for oral consumption until *Legionella*is undetectable in hospital water.

• If cooling towers or evaporative condensers are implicated, the protocol outlined in CDC-EIC Guidelines appendices provides recommendations for further action, as well as recommendations from ASHRAE and others.106(See Supplemental Resources.)

• The efficacy of measures taken to reduce or eliminate *Legionella*should be assessed and modified as needed. Accurate records of control measures and environmental test results for cooling towers and potable water systems should be maintained.

TREATMENTS

As noted, other approaches that have been recommended to prevent or control *Legionella*include ozone, ultraviolet light, chlorine dioxide, or heavy metal ions (i.e., copper/silver ions).77–79,82–88The CDC makes recommendations only for thermal eradication and hyperchlorination as described, but these are effective for eradication of *Legionella*for very brief periods. Analyses of the protective effects of monochloramine are encouraging, and positive results have also been achieved with copper-silver ion treatment.42,51,52,84–86Chlorine dioxide has been used extensively as a disinfectant in other industries as well as in HCFs in other countries with documented effectiveness. Chlorine dioxide does not produce trihalomethanes (THMs) like chlorine, has been found highly useful in controlling biofilm, and is EPA approved.79–83Some recommendations related to eradication remain controversial and unresolved.42,58,106At this point, there is no one method that works consistently to eradicate *Legionella*permanently from water systems, and the 2003 CDC-EIC guidelines make no recommendations beyond heating and chlorination methods.1

OSHA TECHNICAL MANUAL

Several algorithms for approaching *Legionella*problems have been published.58(See also **84. Legionella pneumophila**.) The OSHA online technical manual offers an algorithm for investigation of reported legionellosis cases.74The algorithm is geared more to a nonhealthcare setting and is focused on employees, rather than patients; however, it may be of interest to IPs in HCFs. The manual recommends that a "level 1" investigation be initiated when there is a probable basis for suspecting that the workplace water sources are contaminated with *Legionella*or when there is information that one case of Legionnaire's disease may exist. A "level 2" investigation is warranted when more than one case has been reported at the facility. If an ongoing outbreak is occurring, control measures should be initiated immediately.

Steps for a level 1 investigation are discussed in detail in the manual but are summarized here:

- Obtain an overview of all water systems at the facility.
- Conduct a walk-through investigation of the facility.
- Assess the results of the walk-through investigation to determine the course of action.
- Recommend control actions.

Steps for a level 2 investigation can be summarized as follows:

- Assess water systems as described for a level 1 investigation.
- Conduct a second walk-through survey of the facility and collect water samples.
- Initiate an employee awareness program and monitor current sick leave for new cases.
- Review worker absences to detect other cases.
- Assess results of the worker-absence survey and analysis of water systems.
- Recommend control actions.

Conclusions

The role of infection prevention in evaluating water-associated problems related to construction and routine operational functions in HCFs remains a challenging and exciting one. It is hoped that this overview of issues related to water distribution systems and equipment will assist in risk assessment, plan review and design, and preventive maintenance policies and procedures. As always, infection prevention and control programs are most successful when they facilitate multidisciplinary approaches in planning. Architectural and engineering professionals increasingly recognize the need for collaboration with IPs, especially when they must resolve moisture and water-related fungal problems affecting ventilation. Prevention through planning can save the enormous cost of "rework" while reducing the risks of HAI from the environment. Interaction and integration of efforts with other disciplines by way of the ICRA process or similar collaborative efforts should assist in keeping infection prevention the driving force during routine maintenance and construction/renovation processes.

Future Trends

A number of issues and concerns remain and will require continual research and evaluation of methods to further improve patient outcomes, as noted in the APIC state-of-the-art report on construction and renovation (see Supplemental Resources). Some include the following:

• Hand-washing sink and faucet designs: The degree of risk associated with various faucet and sink designs has not yet been determined and may be resolved by examining other methods of water purification and/or sink design.

• Plumbing and preventive maintenance systems: Better or alternative methods (e.g., ozone to reduce or eliminate *Legionella*contamination in potable water systems) continue to be sought. In the setting of continued low-level contamination, determination of the dose response relationship from potable water exposures resulting in disease remains elusive. This remains key to preventive water system treatments. The value of environmental cultures for *Legionella*spp. remains elusive, in part reflecting the hypervariability of levels of contamination between locations.

• Water quality: Questions also remain regarding treatment of water used to disinfect medical equipment. A controversial and unresolved question remains regarding routine sampling of rinse water used in automatic endoscopic reprocessors. The need and/or feasibility of using sterile water for direct patient care also must be further investigated.

• Filtration: Some have suggested that additional interventions such as filters at point of delivery of water can assist in prevention of transmission of waterborne pathogens such as *Legionella*spp.118,119However, questions remain over whether this intervention is cost effective. In addition, point-of-use filtration requires maintenance and change of filters that increase both of these variable cost elements. Advocates of these devices also point to installation into fixtures of rooms of patients who are immunocompromised. The ability to precisely predict admission of these populations to certain rooms is unlikely because there is a trend toward a universal room that could accommodate any patient. More study is warranted before widespread adoption of this approach.

• Efficacy of remediation protocols: Controlled studies on the efficacy and safety of current or newer antifungal treatments after severe water damage are needed. Clearer determinations regarding the safety of damaged drywall left in place, versus its removal, needs further elaboration. Other studies are needed to determine the efficacy and safety of other types of materials for remediation (e.g., fiberglass-reinforced drywall).

• Surfaces: Identification of better materials and surfaces that resist moisture and resultant contamination from microorganisms warrants further study.

• Environmental sustainability: There is growing emphasis on the need for stewardship of the global environment well beyond the HCF campus. This includes conservation of potable water use, recovery of "gray water," and the use of low-flow showerheads and toilets, water-free urinals, and electronic sensors for faucet control. Conservation of water is especially important for facilities located in arid climates, and this conservation also saves the energy and volume of chemicals needed to treat wastewater. The challenge is maintaining the balance between environmental sustainability without compromising safety of patients or other occupants in HCFs. Practice Greenhealth and Global Health and Safety Initiatives are organizations that are facilitating an environmentally supportive agenda, and those interested are encouraged to visit the websites for these and other similar organizations to learn more. (See Supplemental Resources.)

International Perspective

The ability to provide and sustain the availability of clean water is a global challenge. When considering the multitude of water uses in healthcare settings, the ability to meet the needs of the patients and the HCP providing care is one of great importance. IPs should be knowledgeable regarding the many opportunities for transmission of waterborne illness and work to identify and consider viable options as part of a patient safety program, regardless of the setting or available resources.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Construction and Renovation

Author(s): Lewis Johnson, MS CIH
Industrial Hygienist

Lee Memorial Health System
Fort Myers, FL

Published: December 15, 2015

Abstract

The infection control risk assessment and mitigation processes are important entry points for the active participation by the infection preventionist into the design and oversight of healthcare construction and renovation projects to provide input addressing infection risks to patients, healthcare personnel, and visitors. This chapter addresses the role of infection prevention in the healthcare facility environment during construction and renovation. Following the steps of the infection control risk assessment and mitigation processes, it addresses issues for consideration during the project design phase, construction phase, and before moving into newly constructed or renovated spaces. The background and regulatory aspects of the infection control risk assessment and risk mitigation recommendations processes are described as well as the administrative organization common to healthcare construction and renovation projects.

Key Concepts

- The infection control risk assessment and mitigation recommendations are important components of an infection prevention program, and should be an integral part of construction and renovation planning in a healthcare facility.
- The infection preventionist (IP) should have access to and knowledge of the most current guidelines for design and construction of healthcare facilities published by the American Society for Healthcare Engineering of the American Hospital Association.
- IP leadership is essential in the planning, construction, and acceptance phases of healthcare construction and renovation to protect the health and well-being of healthcare professionals, patients, and visitors.
- Policies and procedures addressing the expectations and responsibilities of the representatives from infection prevention, facilities, plant operations, contractors, and affected program areas are important

when planning and implementing construction and renovation projects in healthcare facilities.

Background

The need to address infection risks created by construction activity in healthcare facilities has been recognized for many years. In 1996, the Guidelines for the Design and Construction of Hospital and Healthcare Facilities (FGI Guidelines) introduced the term infection control risk assessment (ICRA) as a way to plan for infection control needs when designing, constructing, and/or renovating healthcare facilities.[1] The subsequent edition of the FGI Guidelines published in 2001 mandated using an ICRA as a part of the planning and construction process.[2] The 2006 edition of the FGI Guidelines added the requirement for written infection control risk mitigation recommendations (ICRMR) describing how the transmission of biological contaminants from construction zones will be contained and controlled.[3]

While not all authorities with jurisdiction over healthcare construction use the FGI Guidelines, 42 states, The Joint Commission (TJC), and many federal agencies now use them to some degree as a code or reference for evaluating healthcare construction activities.[4] Not all authorities use the full version of the FGI Guidelines or most up-to-date edition for approving building plans.[5] The project architect or manager should be familiar with the version of the FGI Guidelines that applies to the project.

Other organizations and agencies also recognize the importance of infection prevention as a part of construction and renovation in healthcare. In 2000, a paper was published in the *American Journal of Infection Control,* the official journal of the Association for Professionals in Infection Control and Epidemiology (APIC), describing the role of the infection preventionist (IP) during construction projects in healthcare facilities.[6] In 2003, the Centers for Disease Control and Prevention (CDC) included specific recommendations for infection control during construction and renovation work in their guidelines for environmental infection control in healthcare.[7]

Infection Control Risk Assessment

The ICRA provides a formal mechanism for evaluating and addressing potential infection risks created by construction in healthcare facilities. In the current (2014) edition of the FGI Guidelines, the ICRA is a part of the broader Safety Risk Assessment process.[8] According to the FGI Guidelines, the ICRA must address construction design elements related to infection prevention, as well as the infection risk posed by the construction work.

The ICRA should be completed by a construction team involving representatives from infection prevention, safety, engineering, and healthcare professionals (HCP) who represent areas of the facility that are likely to be affected by the construction. The IP's role on the ICRA team is to

1. assess the needs and risks of the patient population that will be affected by the construction;
2. address the infection prevention needs of the patients and HCP that will occupy the space after construction; and
3. provide evidence-based guidance on infection prevention procedures to the project design team.

Additional experts in ventilation, plumbing, specialty materials, and equipment may be necessary depending on the scope of the project.

ICRA Policy and Procedures

Because the ICRA involves multiple departments and outside contractors, it is prudent to establish a policy for ICRAs. This policy should specify

- departmental responsibilities for each aspect of the ICRA;
- the types of work that fall under the ICRA requirement;
- definitions of the terms used in the ICRA;
- procedures for validating compliance with the ICRA; and
- any record-keeping requirements related to the ICRA process.

Forms and templates to facilitate completion of the ICRA process are available from APIC, the American Society for Healthcare Engineering (ASHE), TJC Resources, as well as other sources.[9,10,11] The local authority with jurisdiction over healthcare construction may have a preferred template design for use in ICRA documentation.

ICRA Elements in the Design Phase

The ICRA process should begin early in the project planning phases to ensure that plans and drawings accurately incorporate the recommendations of the ICRA team. Making changes late in the design process can be expensive and may delay the project schedule. In general, the ICRA should influence the facility design, the procedures to prevent exposure from construction debris, and the selection of equipment and surfacing materials to manage infection risk. The FGI Guidelines specify design elements that the ICRA must address[8]:

1. Isolation rooms for protective environments and airborne infection isolation
2. Special heating, air conditioning, or other ventilation needs
3. Water and plumbing system issues
    a. The number, types, and location of hand washing and disinfection stations, as well as emergency eyewash and shower stations
    b. Plumbing system design to address potential infection risks from waterborne pathogens
4. Selection of surface finishing and furnishing materials for infection prevention isolation rooms (general)

When determining the number, types, and design of isolation rooms, consider the patient population, mission, and program goals of the facility; experience with communicable diseases; and other available resources within the community. Isolation rooms may be an airborne infection isolation (AII) room, a protective environment (PE) room, or a room that provides both AII and PE. Rooms designed as a combination AII/PE room must also have an anteroom. While combination AII/PE rooms are permitted, the ANSI/ASHRAE/ASHE ventilation standard included in the FGI Guidelines does not support designs in which the isolation room may be converted from an AII room to a PE room by switching the airflows.[12]

The position in the standard prohibiting switchable isolation rooms is based on the complexity of pressure relationships and concerns for serious patient and healthcare provider outcomes if errors were to be made in correct room pressurization.

Infection Prevention: Design, Hazards, Implications, and Interventions

Number of Airborne Infection Isolation Rooms

Provide a sufficient number of AII rooms in newly designed or major renovated facilities. According to the FGI Guidelines, at least one AII room should be provided in an acute care facility. Program assessment should consider the expected patient population and the services provided. The FGI Guidelines do not require AII rooms for long-term care facilities unless so determined by the facility during the ICRA.[13]

Design of Airborne Infection Isolation Rooms

AII rooms have airflow from the corridor into the patient room, where air inside the AII room directly exhausts to the outdoors. The AII room design must include a permanently installed device to monitor the required pressure differential between the room and the corridor. AII rooms are not required to have anterooms, but when they are present, the air should flow from the corridor into the anteroom and then into the AII room.

Air recirculation from the AII room to the general ventilation system or through a dedicated air handler unit in the AII room is not permitted in new construction. There is an exception for AII rooms retrofitted from standard patient rooms and where is it impractical to exhaust outdoors. In this situation, recirculation of room air is permitted, provided the air first passes through a HEPA filter. In addition to the ventilation requirements, AII rooms must meet the basic patient room requirements.[8]

Number of Protective Environment Rooms

The ICRA determines the number of PE rooms required. When the ICRA determines that one or more PE rooms are required, the FGI Guidelines specify that at least one PE room must be a combination AII/PE room for highly immunosuppressed patients who have a concurrent infection, such as a cancer patient with varicella (chicken pox).

Design of Protective Environment Rooms

The PE room must be positively pressurized relative to the corridor and adjacent spaces, and must include a permanently installed device to monitor the required pressure differential between the room and the corridor. A combination AII/PE room must include an anteroom in the design, so there must be two devices: one to measure the pressure differential between the room and the anteroom and another to measure the pressure differential between the anteroom and the corridor.

Special Heating, Air Conditioning, or Other Ventilation Needs

The FGI Guidelines require the ICRA team consider whether the anticipated patient population will have special requirements beyond the standard temperature, relative humidity, filtration, or air exchange rate parameters for a healthcare facility. In locations where proper pressure balance relationships are critical to infection prevention, the ICRA team may determine that visual indicators of ventilation air pressure balance are necessary for locations other than AII or PE rooms. (See Chapter **114. Heating, Ventilation, and Air Conditioning** for additional information on heating, ventilation, and air conditioning in healthcare facilities).

Surfaces and Antimicrobials

Hand Washing Stations

The FGI Guidelines define a hand washing station as a sink with a faucet operated without the use of hands, a source or dispenser for cleansing agents, and a method to dry the hands. For some locations, the hand washing station faucet can be controlled by a single lever or wrist blades; at other locations, such as scrub stations and multibed patient rooms, the hand washing station operation must be hands-free and single lever or wrist blade controls are not permitted.[8]

The FGI Guidelines establish the minimum number, types, and locations of hand washing stations, with the need for additional stations determined by the ICRA. Hand washing station design should consider materials and installation to ensure ease and effectiveness of cleaning and disinfection, as well as water pressure regulation, faucet placement, and sink design to control splashing. Determining which styles of currently installed hand washing stations provide ease of use and minimal splashing can help in selecting designs for new installations. Laminated sinks are commonly selected because of the lower initial cost, but life-cycle costs and problems with laminate delamination and water damage to the core material is a consideration for infection control.[14]

The FGI Guidelines specify the types of substrate that can be used for laminate counters with hand washing sinks. Sink counters made from porcelain, stainless steel, or solid-surface materials do not suffer from delaminating due to water damage.

In addition to sink designs, the ICRA team should evaluate options for hand drying, including the types and locations of towel dispensers. Recontamination after hand washing can occur when touching the towel dispenser, so touchless towel dispensers may be considered in some locations.[15] Hot air dryers are permitted under the FGI Guidelines, but paper towels are superior to hand dryers in removing bacteria and minimizing contamination.[16] (See Chapter **115. Water Systems Issues and Prevention of Waterborne Infectious Diseases in Healthcare Facilities** for additional information on waterborne diseases in healthcare facilities.)

Waterborne Pathogens

During the design phase, consider plumbing features that will minimize the likelihood of contamination with *Legionella* and other pathogens, and promote disinfection of the plumbing system if microbial contamination does occur. Avoid stagnant water in plumbing runs or water storage due to low flow, and keep pipe run length as short as possible. Adequately insulate pipes and tanks to maintain temperatures, and ensure that these areconstructed of materials that do not encourage *Legionella* growth.[17] Well-located isolation valves, recirculating plumbing systems, and connections for injecting chlorine or other disinfecting solutions could make it easier to manage responding to a future pathogen outbreak easier. (See Chapter **115. Water Systems Issues and Prevention of Waterborne Infectious Diseases in Healthcare Facilities** for additional information on plumbing and prevention of waterborne infections.)

Selection of Surface Finishing and Furnishing Materials

The selection of surface finishes and furnishing materials is the final ICRA element required in the FGI Guidelines during the planning phase. Ideal surfaces and materials are durable, able to withstand

cleaning and disinfection, and resistant to damage from moisture. Surfaces and materials in patient care areas in particular need to be impermeable to body fluids.

Wall Surfaces

The FGI Guidelines require all walls in healthcare facilities to be washable and require those near plumbing fixtures to be scrubbable and resistant to water damage. Invasive procedure rooms, isolation rooms, and sterile processing areas require a smooth finish free of fissures, open joints, and crevices that could retain or permit passage of dirt particles. Vinyl wall coverings are discouraged because they can trap moisture in the wall, creating the potential for fungal growth, especially when located on exterior walls or where plumbing leaks are likely.[18]

Floor Coverings

Select floor covering based on the needs of the location. All flooring selections should be cleanable and durable. Flooring in invasive procedure rooms, isolation rooms, and sterile processing areas must have sealed seams, including the flooring wrapping up onto the wall. Although carpet may be appropriate in areas where the floor is unlikely to be soiled, and sound attenuation is a factor, it is not appropriate where soiling and exposure to blood and body fluids is likely. The FGI Guidelines provide specific floor design requirements for some types of healthcare spaces. Recommendations for the type of floor surface to facilitate the safe use of patient handling and movement equipment is a part of the Patient Handling and Movement Assessment.[8]

Construction or Renovation Activity

Construction Risks

Infection risks from construction work in or near healthcare facilities come primarily from mold spores carried by air movement. Waterborne pathogens can be a concern in plumbing systems when water becomes stagnant from lack of use during construction or from disruption of accumulated biofilms by the impact of construction work on existing plumbing. In addition to the infection risks, noise, vibration, and odors from construction activities can disturb patients and other building occupants. This is especially a concern for patient care areas such as inpatient and extended care facilities that cannot be vacated during construction. Work on the ventilation system and isolation of portions of the ventilation system in construction areas can have adverse effects on the ventilation balance and temperature in other spaces.

Flooding caused by construction activities can damage materials inside as well as outside of the construction zone. Project managers should ensure construction workers know the location of water shut off valves prior to work on or near plumbing fixtures. Having plans for responding to flooding in place ahead of any flood event can help to ensure a proper response that does not exacerbate the risk of infection.

Infection Control Risk Mitigation Recommendations

In addition to infection risk concerns identified in the design phase, the ICRA team must identify the potential infection risks to patients due to the construction work and develop infection control risk mitigation recommendations (ICRMRs). ICRMRs are written plans describing how the release of potentially infectious agents from the construction activities will be controlled. The ICRA and subsequent ICRMRs consider the potential susceptibility to infection for patients near the construction work, as well

as the likelihood for the construction to release pathogenic organisms. A standardized template describing ICRMRs may be adequate for small, simple projects, while the ICRMRs for larger and more complicated projects may be incorporated into the project drawings and project manual. Examples of standardized ICRMR templates are available from APIC, ASHE, and TJC Resources as well as other sources.[9,10,11] The local authority having jurisdiction over healthcare construction may have a preferred template for use in ICRMR documentation.

Construction Containment Barriers

Construction work zones in healthcare facilities are often enclosed within a barrier system to contain the dust generated as well as potentially infectious microorganisms. These barriers may be constructed of flexible plastic sheeting, rigid plastic, drywall, or other materials.

The materials used to construct the containment barrier must be tested and compliant with the version of the NFPA Life Safety code locally enforced by the authority having jurisdiction. Containment barriers in spaces that are not actively sprinkled spaces must be 1-hour fire-rated walls.[19] In actively sprinkled spaces, the containment barriers do not have to be fire rated, but some jurisdictions do not allow the use of flexible plastic sheeting as a barrier. When the barrier is constructed with drywall sheets, a temporary plastic sheeting containment is often installed first to contain the dust generated by building the drywall containment.

In addition to the physical containment barrier, air is exhausted from the contained space to create a reduced air pressure relative to adjacent occupied spaces. This reduced pressure is referred to as negative pressure and results in airflow from clean adjacent spaces, into the contained work zone, and then out the exhaust. The exhaust may be to the outdoors, or directed back into the building after passing through a high efficiency particulate air (HEPA) filter.

When designing the construction containment, it is important to consider the building's life safety equipment and requirements. Enunciators for fire alarms, alarm pull stations, and sprinkler heads may need to be relocated if the containment will cover or otherwise interfere with their operation. Ensure that sufficient width remains in corridors after containment construction for patient transport as well as code-required width for emergency egress.

Isolating the Ventilation System

The ventilation air supply and return grills within the contained construction space are sealed to keep them from becoming contaminated during the construction work and to prevent the ventilation from interfering with establishing negative pressure as explained below. Active return air ducts that extend through the construction site and serve other locations may be wrapped in plastic sheeting to prevent any leaks into the duct from the construction site.

Exhaust grills with fans on the exterior of the building pulling air out of the space may be left operating to assist with creating negative pressure within the contained space. Whether the existing exhaust systems can be used or must be shut down depends on system design and the results of the ICRA for the space. Exhaust systems with fans in the building pushing air out through the duct should be shut off and sealed to prevent any leaks in the pressurized exhaust duct from spreading contamination from within the contained space. When exhaust systems are left operating, placing filtering material over the grill will help to protect the system from the construction dust.

Shutting off ventilation in the construction zone may affect the ventilation in other parts of the building. The proper air pressure balances in the areas adjacent to the construction zone should be verified after the construction containment is established.

Containment Negative Pressure

Creating a lower or “negative” pressure within the contained work zone helps to prevent the release of airborne infectious agents in the event of a breach in the containment barrier, or when doors are opened to move workers and equipment in or out of the work zone. This negative pressure is created by exhausting air from the contained workspace. If the air is exhausted to the outdoors away from pedestrian traffic and air intakes, all that may be needed is an exhaust fan to pull the air out of the contained work zone. If the air will be exhausted back into the building, or outdoors near an air intake or pedestrian traffic, it must first pass through a HEPA filter. HEPA-filtered, air-moving devices (negative air machines) are designed for this purpose.

Just as HEPA filters used in an operating suite or pharmacy bench are periodically checked and certified, HEPA filters in these negative air machines should be checked to ensure that they are properly installed and not damaged. An improperly installed or damaged HEPA filter can allow contamination from the construction to bypass the HEPA filter and blow out of the contained construction space with the exhausted air.

The FGI Guidelines call for the contained construction space in high-risk areas to have a minimum of negative 0.03 inches of water lower pressure than the adjacent spaces in the building. There is no established amount of negative pressure required for other locations. Too little negative pressure will reduce the effectiveness in controlling emissions from the containment, and too much negative pressure can pull down containment barriers, especially when built with plastic sheeting.

The negative air pressure differential between the contained space and the adjacent spaces should be measured, and the results logged to document that negative pressure was maintained.[7] Digital pressure monitoring devices often will log these data automatically in a file that can be downloaded to a computer or printed. Mechanical devices must be checked periodically and the readings logged manually to create a record. For high-risk or sensitive locations, there are pressure monitoring devices that can alarm and send phone or text messages to alert when the negative pressure is failing.

Portable Containment

For smaller jobs and work above ceilings, portable containment units are available that incorporate the containment barrier and the negative air machine into a system that can be wheeled through a corridor and then set up at the worksite. These devices can have flexible or rigid walls. Some are clear to allow observation of the work occurring inside; others are opaque. Train workers who will use these portable containments units in their proper setup and use. Depending upon where they are stored, and the type of work, these units may require cleaning before being transported through the facility to the job site. Portable containments should be selected after ensuring that they are adequately sized for the workers and tools required to complete the task.

Tracked Dust

Workers should clean loose dust, and any possible infectious agents that may be mixed in with the dust, from their clothes and tools before leaving the contained workspace. A HEPA-filtered vacuum works well for this use. Water used to wipe down tools should be kept clean and rags replaced frequently to minimize microbial contamination in the water. Workers can put on shoe covers before leaving the

contained work zone to control dust. Tacky mats placed at the exit from the contained workspace and promptly changed out when soiled can help to remove dust from shoes and wheels on equipment leaving the contained work zone.

A trash chute is preferred for removing debris from the contained work zone without having to transport it through the facility. The trash chute should be designed to be closed when not in use so that it does not interfere with efforts to maintain negative pressure. When a chute is not possible, debris may be removed using carts. Carts must be covered tightly and their exterior clean before leaving the containment. Transport through the healthcare facility should occur during the lowest activity period, using the agreed upon route as part of traffic flow planning during the ICRA process.

Particle Counters

Laser particle counters are recommended for monitoring the effectiveness of the construction containment by counting particles in the air.[7] A significant increase in the airborne particle counts near the construction containment may indicate a breach or leak. There are no establishedsafe or unsafe particle levels to use for comparison, and the level of particles in the air will vary with the amount of activity in the area, but the counter can be used as a “sniffer” to guide the user to possible sources of elevated particle counts. Particle counters are also useful to verify whether HEPA filters in vacuums and negative air machines are working properly. Many particle counters will operate in an automatic mode, periodically taking and logging samples. This makes and effective method to monitor the effectiveness of the containment controls over extended periods.

Dust Control

Controlling airborne dust from construction, and thereby presumably controlling airborne mold spore levels, is important inside the construction containment as well. Higher levels of airborne contamination will tend to increase the amount of dust leaving the containment site when doors are opened and workers leave the site. HEPA filters used on containment exhaust are very efficient, but not 100 percent. The higher the dust levels in the containment, the more dust will pass through the filter and out of the construction containment with the exhausted air.

Good housekeeping in the containment preventing debris from accumulating on the floor can help to control dust levels. Using HEPA-filtered vacuums rather than standard shop vacuums or dry sweeping will also help to reduce the airborne dust levels inside of the containment. A fine water mist can help clean fine dust from the air. Additional negative air machines can be set up inside the containment to recirculate and scrub the air within the containment.

HEPA-Filtered Vacuum Cleaners

Not all vacuums represented as HEPA-filtered vacuums are equipped with certified HEPA filters or designed so that all of the air entering the vacuum passes through the HEPA filter before exiting the vacuum. Filters added to shop vacuums as an after-market item or claiming to be made from HEPA-filter material without a certification may not deliver the level of filtration and protection expected from a HEPA-filter equipped vacuum. The filters may have leaks or the design may allow air to be pulled though seals that do not seat well.

Outdoor Projects

Construction work outside of the healthcare facility can generate increased airborne contaminates that can be drawn into the healthcare facility through mechanical ventilation fresh air intakes, open doors

and windows, and occupant traffic. The location of building air intakes, occupant walkways, and windows and doors relative to nearby demolition or excavation projects should be considered as a part of the ICRA. Temporary relocation of pedestrian walkways or increasing the level of filtration for ventilation fresh air intakes can be prudent. [7] Adding additional filtration to the intakes and filter loading due to higher than typical airborne dust levels can restrict airflow and affect operation of the ventilation system. For short duration projects, it may be possible to close the ventilation system outside air intakes near the project for a short period.

Water sprays can control airborne dust emissions from demolition or excavation. Water used for dust control should be potable to minimize the potential for aerosolizing possible pathogens or endotoxins from microbial contaminants in nonpotable water.

Working with the Construction Team

Ideally, the healthcare facility will have a policy that describes how the IP works with the construction team to establish and validate ICRMRs. A common model for infection prevention is for the IP to work with other stakeholders in establishing policies and procedures for the work and then to conduct periodic audits to validate compliance with the agreed on policies and procedures. This model can apply to construction work also.

It is not the IP's job to tell a contractor how to do the work—the IP's job is to verify that the work is conducted in a manner that adequately controls the risk of potential infections and complies with the ICRMRs. The IP should work with and through the facility's project manager. Telling the contractor how to do his or her work can result in project problems with schedules, costs, and liability. Conducting periodic interdisciplinary rounds of the construction sites with the project manager, along with safety, security, and contractor representatives, is a good way for the IP to validate compliance with the ICRMRs and ensure any problems get corrected when found.

The IP may consider requiring some level of credentialing for the construction workers and project management staff responsible for implementing infection prevention recommendations. This training may be provided by the facility for contractors coming in to work or be a requirement for more comprehensive third-party training and certification for employees responsible for implementing and evaluating ICRMRs.

Direct supervision of the ICRMRs for large or extended construction projects may exceed the amount of time and resources that a facility IP has available. In these situations, the project may assign the responsibility for validating and monitoring the ICRMRs to the contractor by establishing the types of measurements and assessments to be performed, the frequency, and the acceptable results. Another option is to engage a third-party consultant familiar with healthcare construction to validate and monitor compliance with the ICRMRs.

After Construction and Before Occupancy

The ICRA and contract documents should detail how the containment barriers are to be removed and construction space cleaned when the work is completed. Facility staff should perform a routine cleaning of the space before returning to the area to service. Recleaning and disinfection of surfaces and equipment may be necessary if the contractor has to return to the site to complete or correct any work after acceptance. Check the ventilation system to ensure that it is balanced and operating at design

specifications. Clean any ducts that were not adequately sealed and became contaminated with construction dust before returning them to service.

Air Sampling During or After Construction

The CDC does not recommend sampling for airborne microbial contaminants before, during, or after construction projects.[7] The CDC does recommend active surveillance to monitor for airborne infections in immunocompromised patients and to periodically review laboratory results and postmortem data to identify additional cases of airborne infection that could be related to construction activities. When air sampling for microbial levels is necessary, the sampling campaign must be well designed by an experienced individual to address the complexities inherent in conducting and interpreting the results from this type of sampling.

Conclusions

The IP has an important role in both the design and construction phases of healthcare facilities. Starting with the ICRA process early in design, the IP works with the construction team and clinical staff to identify the potential infection risks, and then to specify materials and designs to best mitigate these risks. For the actual construction work, the IP assists with identifying the potential infection risks and developing the written ICRMRs and then validating that the ICRMRs are correctly implemented and effective. Preparing for these tasks requires that the IP is familiar with the administration and work of construction projects. Resources like the FGI Guidelines and this chapter are important tools in helping acquaint the IP with the construction process and the expectations for infection control during construction.

Abstract

This chapter provides an overview of the intersecting roles of infection prevention and public health within the healthcare system and the community as a whole. Public health is often considered synonymous with disease prevention. Its goal is to promote the health of the entire human population.[1]

Medicine focuses on treating the illness of individuals and public health focuses on preventing morbidity and mortality within communities. To this end, public health provides coordinated leadership and guidance on both infectious and noninfectious conditions to the healthcare community and the general public. More recently, the Centers for Disease Control and Prevention's National Healthcare Safety Network plays a dominant role as a conduit for reporting healthcare-associated infections to Centers for Medicare & Medicaid Services. This chapter discusses public health's primary functions: public health basic principles, public health and infection prevention trends, and, lastly, the global perspective and highlights of collaborative efforts.

Key Concepts

- Interaction between infection prevention and public health.
- Regulatory and reporting structures at local, state, and federal levels.
- Essential public health services: monitoring the health status of the community, diagnosing and investigating health problems in the community, mobilization of community partnerships, development of public policies, enforcement of laws and regulations that protect health, linking people to health resources, assuring a competent health workforce, and researching new insights and innovations to health problems.[2]
- Other public health services: bioterrorism and emergency preparedness, primary care and personal health services delivered or funded by governmental agencies, education, training, and research.

Background

Infection prevention and public health share a common emphasis on disease prevention. Both aim interventions at the environment, human behavior, and medical care. They benefit from ongoing collaborative relationships at local, state, federal, and global levels. Working together, they can provide at the local level a seamless, protective web for patients with communicable diseases, such as pulmonary tuberculosis, as they move across the care continuum. Regulations related to the reporting of notifiable diseases exist to protect the general public from health threats. Infection preventionists (IPs) play a vital role in the notifiable-disease reporting system, often handling the reporting for their organization.[3]Frequent interaction between IPs and public health professionals helps to foster a shared mission and interdependence—detection of a notifiable disease in a hospitalized patient often results in protection of the community's health.

For over 125 years the mission of public health has been to prevent disease and promote health.[4]The United States Public Health Service, established by President John Adams in 1798 and led by the Surgeon General, is a uniformed branch of the federal government. In 1812, the threat of yellow fever, smallpox, and cholera caused Congress to enact the National Quarantine Act.[5]In the late 19th and early 20th centuries following the scientific discoveries in bacteriology and immunology, public health became regarded as the integration of sanitation and medicine. Public health brings together many disciplines and branches of scientists to collaborate in solving complex health issues.[6]

Since those early days, new and emerging issues of public health importance dominated the national landscape. Issues such as food safety, acute and chronic disease prevention, oral health, and access to healthcare were recognized as important disease control and prevention activities. In the 21st century, interest in quarantine and community-based disease control measures reemerged. Severe acute respiratory syndrome (SARS), potentially infectious bioterrorism threats, and the growing possibility of an influenza pandemic would all require communitywide prevention and control measures.[6]

Public health functions at the global, federal, state, and local levels. The World Health Organization (WHO) functions under the United Nation's umbrella and collects information on a number of infectious diseases from countries. At the federal level, the executive order of the president provides the secretary of health and the surgeon general with the authority to isolate and quarantine individuals suspected of having cholera, diphtheria, infectious tuberculosis, plague, smallpox, yellow fever, viral hemorrhagic fevers, SARS, influenza viruses causing or potentially causing a pandemic, and emerging multidrug-resistant microorganism.[7,8]

Each state's statutes provide authority to require the reporting of certain diseases, and allow official investigations and implementation of control measures. Local health departments generally derive their authority from the state health department. The public health authority at the state, county, or city level is assigned to an individual, usually a physician, who has been appointed by a jurisdiction and taken an oath to enforce laws intended to protect the public's health. Diseases reported at the local level are compiled by the states and submitted to the Centers for Disease Control and Prevention (CDC). Notifiable disease summaries and trends are published weekly in the *Morbidity and Mortality Weekly Report*(MMWR).[9]

Ongoing public health disease surveillance and epidemiological support provide necessary information to identify outbreaks or urgent infectious situations of concern for health facilities and the community.

Public health disease surveillance is gathered through systematic collection, consolidation, and evaluation of morbidity and mortality reports, providing key information on the patterns of disease occurrences. Finally, public health offers accessible educational and training materials critical to prevention and control of infectious and emergent diseases to the community and healthcare providers. The CDC's National Healthcare Safety Network (NHSN) is the most widely utilized healthcare infection tracking system. A secure, Internet-based surveillance system, the NHSN houses three former CDC surveillance systems: National Nosocomial Infections Surveillance System, National Surveillance System for Healthcare Workers, and the Dialysis Surveillance Network.[10]The NHSN permits healthcare facilities to collect, analyze, and trend healthcare-associated infections (HAI), multidrug-resistant organisms (MDRO), and healthcare personnel vaccination and blood and blood product transfusion adverse event data. Presently, more than 11,000 healthcare facilities participate in the NHSN. Participating facilities include acute care hospitals, ambulatory surgery centers, long-term care hospitals, dialysis centers, and nursing homes. The NHSN functions as an intermediary for facilities to comply with Centers for Medicare & Medicaid Services (CMS) infection reporting requirements.[11]

In 2009, the American Recovery and Reinvestment Act was signed into law. The Act's purpose was to stimulate the economic recovery and contained provisions to provide funds to state health departments to strengthen their healthcare infrastructure to address HAIs. Each state plan addresses the goal of HAI reduction including MDROs with the ultimate goal of healthcare cost reduction. Prevention partnerships have evolved from state plan implementation.[11]

Basic Principles

Public health has a primary focus on populations with an emphasis on disease prevention.[12]It provides a network of support services and leadership particularly related to infectious and communicable disease control. Key to understanding public health's role is a set of core public health concepts and practices, including basic public health prevention services, definitions, notifiable (reportable) disease reporting, public health surveillance and investigations, and emerging infectious disease threat oversight and leadership.

Public Health Activities and Services

The common themes describing public health encompass organized efforts to: (1) protect and promote human and environmental health, (2) prevent communicable and chronic diseases, and (3) improve health and access to health services for persons with limited resources.[4,5]Public health is defined as "the practice of preventing disease and promoting good health within groups of people, from small communities to entire countries."[6]Public health services include vaccination programs, human immunodeficiency virus/acquired immunodeficiency virus (HIV/AIDS) counseling and testing, public health community education, outbreak investigations and case follow-up, tuberculosis and sexually transmitted infection treatment, and, more recently, bioterrorism, emergency, and pandemic preparedness leadership and response. State public health laboratories provide testing when a new or unusual pathogen is suspected.[11]Nonmedical public health services may include environmental testing of surface and well water, inspection and monitoring of restaurants, and population-based statistics of community health status. In some states and communities, clinic health services are available to uninsured and underinsured residents. Public health nurse and school nurse services may be available as well.

Prevention

Many public health efforts in disease prevention are targeted at populations or at subpopulations; for example, specific age groups, at-risk or behavior-associated groups, groups of persons with the same chronic disease such as diabetics, and those sustaining hazardous exposures. Public health prevention is global and works in partnership with other countries to prevent the transmission, introduction, and spread of communicable disease into the United States and its territories.[6]These efforts may utilize primary, secondary, or tertiary prevention. Primary prevention activities are directed at avoiding disease and disability before it starts. Promoting universal vaccinations serves as primary prevention. Secondary prevention efforts focus on identifying or detecting existing health problems or conditions before they cause serious or long-term problems. Tertiary prevention activities aim to limit or reduce the condition's negative effects. IPs utilize interventions aimed at primary, secondary, and tertiary prevention regularly for both patients and healthcare personnel. Optimizing hand hygiene is primary prevention in action. Tuberculosis skin testing following an unprotected occupational exposure to a patient with active pulmonary tuberculosis exemplifies secondary prevention. Lastly, IPs conduct tertiary prevention when conducting an outbreak investigation.

Notifiable Diseases and Reporting

IPs must be familiar with public health requirements.[9]Notifiable (reportable) infectious diseases are recommended to the CDC by the Council of State and Territorial Epidemiologists (CSTE). CSTE establishes case definitions of diseases and conditions under surveillance. The list of notifiable conditions varies by state.[9]Reportable or notifiable diseases are those of public interest by reason of their contagiousness, severity, or frequency.[9]Each state determines the reportable diseases and conditions for that state and specifies the time frame for reporting and the information to be included in content of the reports. Additional diseases may become reportable as a result of a current outbreak (e.g., influenza cases), a newly emerging condition (e.g., SARS), or to track statewide (e.g., methicillin-resistant *Staphylococcus aureus*[MRSA]).[9]The list of notifiable diseases is updated periodically. Reporting is presently mandatory only at the state level.[9]Outbreaks and suspected outbreaks are also reportable in most jurisdictions. Reports are confidential and usually include basic demographic information, date of onset, city or county of residence, and laboratory testing results, when applicable.[11]This systematic reporting permits public health to investigate individual cases, as well as to develop a baseline of expected cases of diseases or conditions of concern. The most recent update to the nationally notifiable diseases was in 2011.[9]Currently, 91 conditions are nationally notifiable. New diseases or syndromes may be added to the list as they appear. Since notifiable diseases change periodically and vary state-to-state, IPs are advised to remain up-to-date with state notifiable diseases and reporting requirements.

Electronic reporting of the nationally notifiable diseases enhances reporting frequency and timeliness. The CDC receives reports from 50 state health departments, New York City, the District of Columbia, and five U.S. territories through the National Electronic Telecommunications System for Surveillance (NETSS). The CDC released NEDSS, a component of the Public Health Information System, to foster integrated and interoperable surveillance systems at local, state, and federal levels in 2001.[9]Most states and local public health jurisdictions have similar electronic reporting. IPs should request access to their state's electronic reporting system. Names, addresses, and other personal identifiers are not transmitted to the CDC in the case reports of notifiable disease but are retained at the state and local level. The CDC's MMWR publishes provisional weekly reports of notifiable diseases. The final, corrected reports

are published annually in the *MMWR Summary of Notifiable Diseases, United States*and are available in electronic and paper form.

Public Health Surveillance and Investigation

Regulations related to the reporting of notifiable diseases create the framework for public health's surveillance system. For the IP, knowing local and state infectious disease rates and trends is necessary for ongoing comparisons during review of microbiologic and other laboratory reports. Public health typically offers consultation on cluster and outbreak investigation. Any outbreak of disease that is a potential and serious threat to the general public should be reported, even if the specific disease is not listed as a notifiable disease. Particularly when outbreaks persist or overwhelm a facility's infection prevention resources, public health at the local or state level may provide needed assistance or support including laboratory services.[13]State public heath laws permit access to patient records and other personal health information related to communicable disease and outbreak investigations. The IP must be familiar with state regulations.

Emerging Infectious Disease Threat Oversight and Leadership

The ability to detect and contain new diseases was tested several times in the new millennium. SARS, monkeypox, low-level contamination of food, potential novel influenza strains, and emerging MDROs challenge our healthcare and public health infrastructure. The potential need to contain infectious individuals and quarantine persons exposed to infectious diseases triggered a renewed interest in public health laws and authority to protect communities. Emerging infectious diseases and biological threats led to a return of public health's leadership role in our country and communities.[14]The new all-hazards approach to emergency preparedness led to building alliances with traditional emergency preparedness services, healthcare facilities, and community businesses. Whether providing guidance or antibiotic prophylaxis, public health offers the infrastructure healthcare facilities can rely on for the legal authority to gain cooperation of the general public to halt the transmission of disease in the community at lar

Public Health And Infection Prevention Trends

Since the early 1990s, public health has voiced growing concerns about newly emerging and reemerging infectious diseases.[15]The National Center for Infectious Diseases' Emerging or Re-emerging Infectious Disease program has identified more than 50 infectious diseases and conditions. Emerging infectious diseases include newly discovered infections (SARS Co-V); old infectious diseases, thought to be conquered, which reemerged (multidrug-resistant tuberculosis); known diseases gaining a foothold on a new continent (West Nile virus infection and novel influenza); and established infectious diseases that are becoming increasingly drug resistant (MRSA, vancomycin-resistant S. *aureus*, or carbapenem-resistant Enterobacteriaceae). With varying modes of transmission, these infections represent a threat to the general public often resulting in high mortality. In 2013, the CDC released a report to increase awareness and response to the growing threat of antibiotic resistance. More than two million people become ill with antibiotic-resistant infections each year and an estimated 23,000 die annually from these infections. Every major class of bacterial pathogen has shown the ability to develop resistance to one or more of the commonly used antibiotics, and the global crisis of resistance is serious. The CDC's updated report on antibiotic resistance identifies four core actions to combat these deadly infections: preventing infections and preventing the spread of resistance; tracking resistant bacteria; improving the use of today's antibiotics; and promoting the development of new antibiotics and developing new diagnostic tests for resistant bacteria.[14]IPs are on the front lines of emerging infectious disease. With

the changing epidemiology of MRSA, *Clostridium difficile*, and potential pandemic influenza issues, traditional public health measures such as prevention, surveillance, control, and containment are relied upon.

An organized system of surveillance is essential to define disease prevalence for known and new diseases.[15]Public health surveillance is the systematic and routine collection, analysis, and distribution of data. Passive surveillance relies on healthcare providers to submit required reports. Active surveillance is initiated when a new or unexpected health threat occurs and case finding is critical to determine the scope or contain and control disease spread. Syndromic surveillance has been implemented in many large communities and uses nonidentifying information about symptoms of individuals seeking care. Other public health surveillance systems are used to track trends and interventions, identify emerging issues, define public health problems, and monitor the effectiveness of interventions.[16]

When surveillance activities identify concerns, public health investigations provide necessary and timely information regarding the nature and the extent of the illness, as well as guidance on effective prevention and control measures.[17]Generally, state laws and regulations provide public health organizations with the authority to investigate and review medical records for communicable diseases and conditions of concern. IPs may be investigating a hospital-based outbreak and, at the same time, local public health workers may be following up on community contacts and exposed persons, conducting case findings, and determining the extent of the outbreaks in the community. Infectious disease outbreaks that occur in the community or overwhelm a healthcare system require assistance from knowledgeable and experienced public health epidemiologists and public health nurses. Timely distribution of information of public health importance is provided via the Health Alert Network. The Health Alert Network provides disease outbreak and other infectious disease information as well as national disaster information and updates. National, state, and local Health Alert Networks are used by public health to communicate critical health information to healthcare providers. IPs may request to receive health alerts from their local, state, and national public health agencies.

IPs often mirror in their organizations what public health does within communities. The mutual roles in prevention and preparedness and reliance on the science of epidemiology help maintain strong linkages.

Conclusions

The intersecting roles of public health and infection prevention are examined in this chapter. Infection prevention and public health have common interests of preventing and controlling disease. Public health relies on IPs for notifiable disease reporting and identification of potential community outbreaks. Public health provides infectious disease trending, epidemiological support and expertise, coordinated leadership, and guidance, as well as education and training for IPs. Recent worldwide outbreaks of SARS tested their interdependence and strengthened their collaboration, coordination, and communication. The looming threat of pandemic influenza reinforces our common goals of preventing disease and protecting our respective communities. [18]

Future Trends

During the events of the past several years, infection prevention and public health epidemiology and interventions became visible on the world stage. Examples of collaboration between infection prevention

and public health include HCP response to the H1N1 novel strain influenza pandemic and newly emerging MDROs. Current prevention-related public health trends include preventing and controlling emergent infectious diseases collaboration, emergency preparedness and response, including syndromic surveillance, electronic notifiable disease reporting, infection prevention interventions for disasters, and coordination between acute care and public health agencies. The potential for bioterrorist-associated events today requires public health and health facilities to develop response plans, participate in community response readiness activities, develop skills and expertise in decontamination and incident command, and create methods of identifying possible bioterrorist-associated illness.[19] For more information, see **119. Emergency Management**.

International Perspective

Because infectious disease knows no borders and prevention strategies require global awareness and strategies, the CDC developed a worldwide plan in consultation with global public health partners, Protecting the Nation's Health in an Era of Globalization: CDC's Global Strategy for Addressing Infectious Diseases.[20] The six priority areas include: (1) international outbreak assistance, (2) global disease surveillance, (3) applied research on diseases of global importance, (4) application of proven public health tools, (5) global initiatives for disease control, and (6) public health training and capacity building.[20] Experience with SARS and other infectious outbreaks underscores the need to engage global partners in the prevention and control of emergent infectious diseases.[21,22] More recently, the National Center for Emerging and Zoonotic Infectious Diseases developed a strategic roadmap to address a wide range of infectious diseases globally and nationally, including rare deadly diseases such as Ebola hemorrhagic fever as well foodborne illness and HAIs.[23]

Abstract

Increasing numbers of international travelers are selecting exotic destinations in the developing world. Recommendations should be individualized for each traveler and the journey and should account for personal health, health risks of specific destinations, style of travel, and activities anticipated. Immunizations are the cornerstone of protection for the traveler, but medications can be employed to prevent or treat a diverse array of other problems, such as malaria, traveler's diarrhea, motion sickness, and altitude sickness. Contingency plans should also be made for where to turn in the event of a medical emergency. Given the rapidity of change in the global health situation, those providing information need to be certain that their recommendations contain the latest and most accurate information possible.

Key Concepts

Critical steps in providing advice to travelers include:

- Reviewing medical and vaccination history
- Confirming itinerary (i.e., the names of countries and the order in which they will be visited)
- Determining required immunizations
- Determining other recommended immunizations, based on the risk of the itinerary
- Reviewing contraindications
- Certifying and recording immunizations on an international certificate of vaccination
- Providing needed prescriptions
- Providing written educational materials whenever possible

Background

The number of people traveling abroad on an annual basis has increased dramatically during the past 25 years. Travel to the developing world presents a unique set of challenges for travelers and the physicians providing advice to them. Recommendations should be personalized for each traveler and journey, accounting for personal health, health risks of specific destinations, style of travel, and activities anticipated.[1]

A variety of sources of up-to-date information exist to assist the primary care physician in counseling the prospective traveler. The most authoritative single source is *Health Information for International Travel 2014,*a publication of the Centers for Disease Control and Prevention (CDC).[2]This source, often called the Yellow Book, is updated on a regular basis and available for a fee from the Government Printing Office. It can also be viewed online and printed through the CDC's website. (The CDC website and a variety of others providing important information regarding international travel together with their uniform resource locators [URLs] are listed in Supplemental Resources at the end of this chapter.)

Basic Principles

Concerns of the international travel medicine clinic beyond those for vaccine-preventable diseases can range from the intricacies of chemoprophylaxis against malaria to the more mundane advice for avoidance of illness associated with swimming. Although many of these concerns are associated with geography, climate, and environment and do not often change rapidly, they are nonetheless critical for maintaining good health while abroad.

Motion Sickness

Motion sickness may be a problem for those aboard cruise ships or other boats, airplanes, and even cars. Most individuals who face such problems while traveling may have encountered them before and know in advance what works for them under most circumstances. Dimenhydrinate and meclizine are two over-the-counter (OTC) medications that have withstood the test of time, work well for a variety of persons, and can be taken in anticipation of need. They are short acting and must be taken periodically. The transdermal scopolamine patch can be applied only once every 72 hours and still maintain effective delivery of medication. It may be especially useful if long periods of motion-induced nausea, such as might occur aboard ship, will be encountered.

Insect Bites

Recommendations to prevent insect bites include wearing appropriate clothing, using bed nets, and using appropriate insecticides. Appropriate clothing may include permethrin-sprayed clothing, long-sleeved tops, and closed-toe shoes. The U.S. Environmental Protection Agency (EPA) has approved four formulations of insecticide as being protective. These include DEET, picaridin, oil of lemon eucalyptus, and IR3535. Travelers should be sure to apply insecticide after applying any sunscreen to ensure that they are well protected.

Food and Water Risks

"Don't drink the water" is an often-heard warning for persons traveling to developing countries. Although it is a good start for protection, the warning needs to be extended for maximum effect. In some areas, milk is not pasteurized, and ice can never be assumed to be safe because freezing does not kill most pathogenic bacteria. The safest beverages are wine and beer, which are universally pasteurized, and

carbonated drinks. For maximum safety, travelers should only consume food that has been thoroughly cooked and is served hot or fruit that can be peeled by the traveler. In addition, it is important to remind travelers to not use the water for brushing their teeth. A safe reminder is to have travelers leave a bottle of water in their bathroom. Travelers should also be advised to check the seals of purchased water bottles and not to drink any water from a bottle that appears to have been tampered with.

There are occasions when travelers will not have easy access to bottled water, so it is important that they have recommendations for water sterilization. Methods for water disinfection include heat, filtration, chlorine or iodine, and ultraviolet light. More information about each type of disinfection methods and advantages and disadvantages to each are available in the CDC Yellow Book.[2]

Malaria

Malaria prevention is one of the most important functions of travel medicine. It rests on appropriate use of insect repellents and barriers, such as window screens and mosquito nets, as well as the use of medication in the form of chloroquine, mefloquine, atovaquone/proguanil, and doxycycline that suppress the red blood cell stage of the disease but cannot completely eradicate all types of malaria. For that reason, persons returning from the tropics who develop any symptoms such as fever, chills, or sweats after completing prophylaxis should be evaluated for malaria.

Malaria medication may vary widely in cost, side effects, and how often the medication is to be taken before, during, and after travel. This information should be taken into account when determining what medication to prescribe for a traveler.

Traveler's Diarrhea

Although referred to by the informal name of "Montezuma's revenge" in some regions, traveler's diarrhea known by any of its other terms in different regions of the world can be serious. Prophylactic treatment with antibiotics is no longer considered appropriate or advisable because it is likely to lead to the development of resistant organisms. Moreover, the immediate use of medications such as ciprofloxacin usually dramatically limits the duration of the illness. In some countries and areas, there are ciprofloxacin-resistant bacteria and azithromycin may be provided to the traveler. Loperamide may also be added for more acute or distressing symptoms.

Cruise Ship Travel

Travelers boarding a cruise ship are by no means insulated from travel-related illness. Those affected by motion sickness may wish to take medication for prevention or control of symptoms. If the ship will be docking at ports in countries with special risks for infectious diseases, the appropriate vaccines should be administered. If travelling in the spring or summer, individuals should consider getting an influenza vaccine if they did not receive it during the prior winter season. This is important because influenza outbreaks have occurred during the off season on ships that bring together persons from around the world, including the southern hemisphere, where the flu season occurs during the months considered summer in the northern hemisphere. Finally, traveler's diarrhea, especially due to norovirus, has become more common in recent years. Because norovirus can spread quickly, attention to sanitation/hygiene aboard a cruise ship is especially important. When choosing a cruise ship, individuals may wish to review its most recent sanitation report at the CDC website.

Altitude Sickness

Persons who usually live at lower altitudes may encounter serious problems when venturing to mountainous areas or other higher elevations, especially if periods of long walking or other exertion may

be required. Such problems range from a mild or moderate headache and difficulty sleeping to acute pulmonary or even cerebral edema. Whenever possible, it is best to try to acclimate to the higher altitude slowly over a period of several days through gradual ascent. When this is not possible or practical, use of prophylactic agents such as acetazolamide may be considered. These medications may be started 1 to 2 days before the ascent and are usually maintained for 24 to 48 hours after arrival at the final altitude. Although they may be extremely helpful, descent to lower altitude or the use of oxygen and emergency medical care should be considered if a major problem develops. More recently, nifedipine in a dose of 10 to 20 mg every 8 hours or sildenafil may be helpful in preventing high-altitude pulmonary edema in susceptible persons or in treating it once it occurs. Moreover, dexamethasone in doses of 4 mg every 6 hours is helpful in treating high-altitude pulmonary edema.[2]

Injuries

Overall, injuries are a more common cause of medical consultation than illnesses when traveling in a foreign country. Traffic accidents are a particular risk. Travelers may be unfamiliar with different rules of the road, driving conditions, congestion, or traffic flow. Moreover, they may be driving cars with no seat belts or with less-than-optimal maintenance. It is always advisable to limit nighttime driving to urban areas. Risks of road travel apply to those on motorcycles, bicycles, and mopeds, so pedestrians should maintain special alertness when crossing streets. The other particular concern for travelers is the risk of fires. Anyone checking into a hotel should locate primary and secondary escape routes.

Animals

Although direct contact with wild animals generally should be avoided even in developed nations, feeding or petting dogs and cats not known to be immunized against rabies is not advised when traveling in countries where rabies is present. Any animal bite from a mammal should receive prompt evaluation by a medical practitioner, including consideration of the need for rabies treatment. In addition, persons bitten by a snake should seek medical attention and determine the need for antivenom.

Swimming

Unfortunately, swimming in almost any body of unchlorinated water can pose a health risk for travelers because contaminated water may cause skin, eye, ear, or systemic infections ranging from schistosomiasis to leptospirosis. If there is any uncertainty about the safety of any given freshwater or saltwater area, travelers should not swim or wade in it.

Immunization

The CDC's *MMWR Recommendations and Reports,*a series that documents the recommendations of the Advisory Committee on Immunization Practices (ACIP), focuses on travel-specific immunizations. Because of space limitations, it does not detail routine immunizations that should be updated regardless of plans for international travel, but on the following vaccines: Hepatitis A, Japanese encephalitis (JE), meningococcal disease, rabies, typhoid fever, and yellow fever.

General Considerations for International Travel

Vaccinations are often recommended or required for the traveler; however, it is important to remember that no vaccine is 100 percent effective in protecting against illness. Vaccination is no substitute for taking precautions to reduce exposure to pathogenic agents. Specifically, for the prevention of enteric diseases, general food and water safety precautions should be employed:

- Avoid all potentially contaminated food and water, including ice.
- Avoid foods that are not adequately cooked and served hot, especially fish/shellfish.

- Eat only cooked vegetables or fruit that can be peeled by the traveler.
- Consume carbonated beverages or those made with boiled water, such as coffee and tea. Because beer and wine are universally pasteurized, they may also be considered safe. Milk is not universally pasteurized and so may be suspect in certain locations.[2]

For protection against mosquitoes and other insect vectors of disease, travelers should sleep in well-screened quarters or use mosquito nets and wear clothing that covers most of the skin surface when outdoors during feeding periods for the insects. Permethrin may be sprayed on clothing or bed nets for additional protection. Insect repellents, preferably those containing 30 to 35 percent DEET, should be applied to exposed skin surfaces. A pyrethroid-containing flying insect spray should be used in living and sleeping areas during evening and nighttime hours. Regular inspection of the skin for attachment of ticks is appropriate where tickborne infections are a concern.[2]

Travel Health

U.S. PUBLIC HEALTH SERVICE RECOMMENDATIONS

REVIEW OF ROUTINE IMMUNIZATIONS

Individuals should review of their immunization records with their physician or other medical provider as the first agenda item in t travel preparation. Routine immunizations should be evaluated, including tetanus, diphtheria, and pertussis/tetanus and diphtheria (Tdap/Td); measles, mumps, and rubella (MMR); polio; varicella; *Haemophilus influenzae*type b (Hib); Hepatitis A and Hepatitis B.

Polio

Poliomyelitis remains an important risk for travelers to many of the countries of Africa, southern and southeast Asia, and the Middle East. All travelers to these destinations should ensure that they are immune to polio. There have been no cases of polio in the western hemisphere due to wild-type polio virus since 1991. However, a recent outbreak of poliomyelitis was noted in May 2013 in Somalia and a cluster of cases found in Syria in October 2013.[3,4]All persons traveling to countries where polio has not been eradicated should receive a primary series (at least three doses) of either inactivated polio vaccine (IPV) or oral polio vaccine.

Because IPV contains streptomycin, neomycin, and polymyxin B, persons with a history of an anaphylactic reaction to one of these antimicrobials should not receive the vaccine. In general, it is advisable to avoid polio vaccination in pregnant women unless immediate protection is required.[5]

Breastfeeding is not a contraindication to vaccination in either mother or child.

Varicella

Because the varicella-zoster virus circulates worldwide and routine use of varicella vaccine is low outside the United States, the risk to travelers may be significant. In tropical regions, chickenpox occurs later in childhood or in adolescence; therefore, the lack of interaction with small children while traveling does not eliminate the exposure risk for adults in these areas. Adults at risk should be immunized regardless of travel plans.

All persons traveling abroad should have evidence that they are immune to varicella, given one of the following:

- A personal history of varicella or shingles, based upon a healthcare provider's diagnosis
- Laboratory evidence of immunity; because more than 90 percent of adults—including 70 to 90 percent of those with no reliable history of chickenpox—are immune to varicella, serologic testing before vaccination may be cost-effective.
- Proof of receiving one (if less than school age) or two doses (if school aged or older) of varicella vaccine, each given no earlier than 12 months of age and no sooner than 28 days apart
- Birth in the United States before 1980

Persons with severe allergy to gelatin or neomycin, women known to be pregnant, and persons with immunosuppressive disorders should not be vaccinated.[2]

IMMUNIZATIONS THAT MAY BE REQUIRED UNDER INTERNATIONAL HEALTH REGULATIONS

Yellow Fever

Yellow fever is a viral disease transmitted by a variety of mosquito vectors to humans in South America and Africa. It causes a severe form of hepatitis with jaundice, from which the name is derived. There are three epidemiologically distinct forms of yellow fever: (1) urban, (2) intermediate, and (3) sylvatic or jungle.[6]It was estimated in 2013 that in Africa between 29,000 and 60,000 deaths would occur due to yellow fever.[6]It is estimated that travelers visiting Africa during the endemic season have a 1 in 267 risk of illness and a 1 in 1,333 risk of death from yellow fever.[6]

All yellow fever vaccines currently available contain live-attenuated virus. Because of this, it is important to note that inactivated vaccines can be administered simultaneously or at any time before or after infection; however, other live-attenuated vaccines should either be given simultaneously, or after a waiting period of 30 days, because the efficacy of live-attenuated vaccines may be affected if given sooner.[2]The vaccine must be stored at temperatures of between 5°C (41°F) and -30°C (-22°F) and preferably frozen below 0°C (32°F) until reconstituted with sterile saline. Multiple-dose vials must be held to temperatures of 5°C to 10°C (41°F to 50°F) after reconstitution; all doses must be administered within 1 hour after reconstitution or discarded.[6]

PERSONS LIVING IN OR TRAVELING TO ENDEMIC AREAS, SITES OF OUTBREAKS, AND COUNTRIES WITH MANDATORY REQUIREMENTS

Any person at least 9 months of age traveling to parts of South America or Africa where yellow fever transmission is a risk should be vaccinated. In general, the CDC also recommends vaccination for persons going outside of urban areas in countries that reside in the yellow fever endemic zone. It is essential to consult the CDC Yellow Book and the accompanying list of affected countries and endemic zones to obtain a current and fully informed recommendation. Infants between 4 and 9 months of age may be considered for vaccination if their destination includes countries where yellow fever is prevalent and when protection without vaccination cannot be guaranteed. Under no circumstances should infants under 4 months receive yellow fever vaccine because of the risk of encephalitis.

Vaccine Certificate Requirements

Under the current International Health Regulations adopted by the World Health Organization (WHO), countries may require an international certificate of vaccination (ICV) only against yellow fever from travelers. Smallpox was deleted from the list in 1982, and no country officially requires cholera vaccination at this time. The ICV (or yellow card) must be filled out in all details or it is not considered valid.

Yellow fever immunization must be certified by affixing a uniform stamp on the appropriate line of the ICV and must be signed by a licensed physician or his/her designate. Signature stamps are not acceptable.

In the United States, yellow fever vaccine can be administered only at an approved yellow fever vaccination center, as designated by state or territorial health departments. Vaccine recipients should receive an ICV, which is then completed, signed, and validated with an official certification stamp.

Vaccine Dosage

The dosage is the same for all ages: a single subcutaneous injection of 0.5 mL of reconstituted vaccine. See Table 118-5.

Booster Doses

International health regulations stipulate revaccination at intervals of 10 years; however, immunologic evidence suggests that immunity lasts for significantly longer and perhaps for life.

Reactions

Generally, reactions to yellow fever vaccine are mild, with 2 to 5 percent of recipients reporting headaches, myalgia, low-grade fevers, or minor symptoms for less than 10 days. Fewer than 2 of 1,000 recipients have to modify their regular activities as a result. Immediate hypersensitivity reactions, including rash, urticaria, or asthma, are uncommon, with an incidence of less than 1 per million, and occur primarily among persons with a history of egg allergy. (Persons with a history of egg anaphylaxis should not receive yellow fever vaccine.) More recently, there have been reports of more severe reactions occurring in elderly individuals, resulting in cautionary advice from the CDC to administer the vaccine only to persons truly considered at risk for the disease.[2]

Precautions and Contraindications

1. Age. As noted, infants younger than 4 months should not be vaccinated due to the risk of encephalitis. Travelers over the age of 60 should be advised that side effects and risks are often increased as compared to younger populations.
2. Pregnancy. If an international travel requirement exists without a corresponding real risk of viral infection, a waiver letter should be obtained for pregnant women. Pregnant women who must travel to areas at high risk for transmission should be vaccinated because the theoretical risk from vaccination is far outweighed by the real risk of yellow fever infections (Table 118-6).
3. Altered immunity. Because of the theoretical risk of encephalitis, persons with suppressed immune systems, including those with acquired immunodeficiency syndrome, human immunodeficiency virus (HIV), leukemia, lymphoma, generalized malignancy, or those with immune suppression due to corticosteroids, alkylating agents, antimetabolites, or radiation, should not be vaccinated. In such events, patients should be instructed in appropriate methods of avoiding mosquito bites and given the vaccination waiver by their physicians. Those with asymptomatic HIV infection who cannot avoid yellow fever exposure should be given the choice of vaccination. If necessary,

measurement of the neutralizing antibody response to immunization may be requested from the state health department or the CDC.

4. Hypersensitivity. Persons with anaphylactic reactions to eggs should not be given the vaccine. Those able to eat eggs or eggs products are not considered at risk. If a hypersensitivity to eggs does exist, a letter of waiver should be written on stationery with an official health department stamp. It is also possible to do an intradermal skin test for hypersensitivity under close supervision using directions supplied in the package insert.

Letters of Waiver

If international travel requirements are the only reason to vaccinate a pregnant woman, a person with reduced immunity, or a person with hypersensitivity to eggs, a letter of waiver should be written by the physician on letterhead stationery and affixed with the uniform stamp used to validate the ICV.[2]

VACCINES THAT MAY BE RECOMMENDED FOR USE SPECIFICALLY BY INTERNATIONAL TRAVELERS

HEPATITIS A

Disease

Transmission is by the fecal-oral route, involving a variety of vehicles, including contaminated food (e.g., fruits, vegetables, other foods that are handled extensively but not cooked) or water (including ice), shellfish harvested from sewage-contaminated waters, or by direct person-to-person contact.

Epidemiology

Hepatitis A is highly prevalent throughout the developing world. Consequently, Hepatitis A vaccine is recommended for all persons traveling to or residing in countries with intermediate to high risk for transmission, which includes most areas outside the United States, Western Europe, Australia, New Zealand, Japan, and Korea.[7](Visit the CDC website and refer to the map on the National Center for Infectious Diseases Travelers' Health page for Hepatitis A.)

Vaccine

There are three vaccines licensed by the U.S. Food and Drug Administration for use in the United States. They are formulated with inactivated vaccine adsorbed to the adjuvant aluminum hydroxide and should be given by intramuscular (IM) injection in the deltoid. Each vaccine has a corresponding pediatric formulation containing half the amount of antigen for use in children and adolescents. Vaccine efficacy is shown to be about 94 percent.[7,8]

Table 118-1. Recommended Doses of Hepatitis A Vaccine[2]

Table 118-1 Recommended Doses of Hepatitis A Vaccine

Group	Age (y)	Dose (EL U)	Volume	Number of Doses	Schedule Months
Havrix					

Children and adolescents	1–18	720	0.5 mL	2	0, 6–12
Adults	≥ 19	1,440	1.0 mL	2	0, 6–12
Vaqta					
Children and adolescents	1–18	25 units	0.5 mL	2	0, 6–18
Adults	≥ 19	50 units	1.0 mL	2	0, 6–18
Twinrix					
Adults standard regimen	≥ 18	720 EL U/20 µg	1.0 mL	3	0, 1, 6
Adults accelerated regimen	≥ 18	720 EL U/20 µg	1.0 mL	4	0, 7, 21 days + 1 year

From Centers for Disease Control and Prevention. *Health Information for International Travel*, 2014. Washington, DC: U.S. Government Printing Office, 2014 (known as the Yellow Book).

Scheduling and Administration

Two doses of vaccine, given at time 0 and 6 to 12 months later, are recommended to assure long-term persistence of antibodies (see Table 118-1). Persistence of protective levels of antibody is predicted for a duration of at least 20 years. All inactivated vaccinations are interchangeable, including combination vaccinations containing Hepatitis A.[7]

Reactions

Side effects among users of the Havrix preparation include soreness at the injection site, headache, and malaise. Among children, the most common side effects were injection site soreness, feeding difficulty, headache, and injection site induration.

The most common side effects among adult recipients of Vaqta were tenderness, pain, and warmth at the injection site and headache. Among children receiving this vaccine, the most common symptoms were pain, tenderness, and warmth at the injection site.[2]

Contraindications

Neither vaccine preparation should be given to persons with a history of an allergic reaction to alum. Havrix should not be given to those who have hypersensitivity to the preservative 2-phenoxyethanol.

The risks and benefits of disease and vaccination should be weighed when considering vaccination of a pregnant woman.

Hepatitis A Antibody Screening

Screening for antibodies to Hepatitis A may be reasonable in persons with a likely clinical history or high probability of prior infection (based on age or long-term residence in an endemic area) if the cost of

screening is meaningfully lower than that of immunization and if screening will not significantly delay subsequent immunization.[8]

JAPANESE ENCEPHALITIS

Disease

JE is a mosquito-transmitted viral infection occurring in many parts of Asia that causes inflammation of the central nervous system. Although most cases occur with no recognizable symptoms, the case-fatality rate is about 30 percent, and neuropsychiatric sequelae occur in as many as 50 percent of survivors of clinically evident cases.

Epidemiology

Risk of infection correlates with a number of factors, including age, occupation, recreational exposure, and gender. In endemic regions of the world, children have the highest rates of infection. For specific information about individual countries, a detailed list can be found at the CDC website.

Fortunately, the risk for short-term travelers, especially those who visit only urban areas, is low. Consequently, JE vaccine is not recommended for all travelers to Asia. Travelers at highest risk include persons planning an extended stay of a month or longer in rural, agricultural, or other endemic areas. Vaccination should be considered for short-term travelers who will have extensive exposure due to outdoor activities during evening and nighttime hours, such as camping, bicycling, or agricultural fieldwork. A more detailed consideration of the vaccine may be found in the review by Wilder-Smith and Halstead.[9]

In high-risk areas, travelers should try to use bed nets if air-conditioned or well-screened rooms are not available. Insecticidal sprays, insect repellent (preparations with 30 percent DEET are preferred), and protective clothing to help prevent mosquito bites are also important.

Vaccine

In 2009 Ixiaro became an approved vaccination for JE and was originally approved for travelers 17 years of age and older. In May 2013, the approval for JE vaccine was expanded to children aged 2 months to 16 years. See Table 118-2 for more information.

Reactions

Local and mild systemic reactions, such as fever, headache, myalgia, and malaise, occur in approximately 10 to 20 percent of vaccine recipients. More severe allergic reactions, such as urticaria, angioedema, respiratory distress, and anaphylaxis, may occur within minutes or as long as 2 weeks after vaccination. Vaccine recipients should be observed for 30 minutes after injection and should be advised to report any significant symptoms promptly. It is advised that the last dose of vaccine not be given less than 10 days before initiation of travel so that prompt care may be rendered for adverse reactions, if necessary.

Contraindications

Persons with a history of multiple allergies, especially urticaria or angioedema, are at higher risk for reactions to JE vaccine. Anyone with a history of an allergic reaction to a mouse-derived vaccine or to

JE vaccine specifically should not be vaccinated. Vaccine administration during pregnancy generally should be avoided, except in situations of high, unavoidable risk of exposure.[2]

Table 118-2 Japanese Encephalitis Vaccine Recommendations

Vaccine	Trade Name (Manufacturer)	Age	Dose	Route	Schedule	Booster[1]
JE vaccine, inactivated	Ixiaro (Intercell)	≥ 17 years	0.5 mL	IM	0, 28 days	≥ 1 year after primary series
3 years through 16 years	0.5 mL	IM	0, 28 days	Data not yet available		
2 months through 2 years	0.25 mL	IM	0, 28 days	Data not yet available		

From Centers for Disease Control and Prevention. *Health Information for International Travel, 2014.*Washington, DC: U.S. Government Printing Office, 2014 (known as the Yellow Book).

MENINGOCOCCAL DISEASE

Disease

Infection with *Neisseria meningitidis* causes septicemia with or without disseminated intravascular coagulation or acute meningitis. With early diagnosis and rapid antibiotic treatment, the case fatality rate has dropped from 50 percent to around 10 percent.

Epidemiology

In the sub-Saharan (Sahel) region of Africa, local outbreaks or epidemics of group A meningococcal meningitis occur frequently during the dry season, which typically extends from December to June. This is particularly true in the savannah areas extending from Mali to Ethiopia, an area of meningococcal meningitis prevalence.

The risk for most travelers to this region of Africa is low. Nonetheless, due to limited active surveillance in the area and the severe consequences of infection, travelers to this region during the dry season should be vaccinated, especially if significant contact with the local population is planned.[2]

Vaccine may be required for pilgrims to Mecca, Saudi Arabia, during the Hajj and Umrah. Vaccination is recommended for travel to any country experiencing an epidemic due to a vaccine-preventable strain (A, C, Y, W-135), as generally recognized by issuance of a CDC and or WHO travel advisory. Recently, outbreaks of meningococcal meningitis have occurred in Benin, Burkina Faso, Chad, Central African Republic, Côte d'Ivoire, Gambia, Ghana, Mali, Nigeria, and Sudan.[10]

Vaccine

Beginning in 2005, the vaccine preferred for persons 11 to 55 years of age is a conjugated tetravalent formulation of A, C, Y, and W-135 capsular antigens. Its preferred status relates to its ability to provide long-term immunity and to confer herd immunity by reducing nasopharyngeal carriage. The duration of

immunity is unknown but appears to be at least 5 years. The polysaccharide vaccine is the only one recommended for use in travelers over the age of 55.[2] See Table 118-3.

Reactions

Although severe reactions are uncommon, mild local reactions such as erythema at the injection have been reported.

Contraindications

Persons with acute illness should defer vaccinations until their condition improves. The vaccine is contraindicated for those who have a severe allergic reaction to any of the components of the vaccines. Menactra is contraindicated in those with an allergy to dry natural rubber latex; however, the polysaccharide vaccine is an acceptable alternative for those individuals.[2]

RABIES

Disease

Rabies infection causes an acute and almost uniformly fatal encephalomyelitis. Presenting as vague symptoms such as dysesthesias, the disease progresses to cause weakness, paralysis, spasm of swallowing muscles, altered mental status, and convulsions.

Epidemiology

The most common means of transmission is through animal bite wounds, though contamination of open cuts or mucous membranes by infected saliva without bite exposures is possible. In many areas of the world, canine rabies is highly endemic. In foreign countries where rabies is endemic, bites of any mammalian species should be evaluated for the consideration of rabies prophylaxis.

Table 118-3 Meningococcal vaccine recommendations

Vaccine	Trade Name (Manufacturer)	Age	Dose	Route	Schedule	Booster
Meningococcal polysaccharide diphtheria toxoid conjugate vaccine	Menactra (Sanofi Pasteur)	9–23 mo 2–55 y	0.5 mL 0.5 mL	IM IM	0, 3 mo 1 dose	If at continued risk[1]
Meningococcal oligosaccharide diphtheria CRM_{197} conjugate vaccine	Menveo (Novartis)	2–55 y	0.5 mL	IM	1 dose	If at continued risk[1]
Meningococcal polysaccharide vaccine	Menomune (Sanofi Pasteur)	≥ 2 y	0.5 mL	SC	1 dose	If at continued risk[2]

From Centers for Disease Control and Prevention. *Health Information for International Travel, 2014.* Washington, DC: U.S. Government Printing Office, 2014 (known as the Yellow Book).

Most of the countries of the world harbor a rabies risk. Notable exceptions are those listed in Table 118-4, which shows countries for which no rabies cases were reported during 2012. The decision to administer vaccine before international travel should be based on (1) the incidence of rabies in the countries visited, (2) the length of stay, (3) the types of activities planned, and (4) the availability and types of vaccine locally.[11]

Vaccine

Pre-exposure prophylaxis may be completed with a three-series injection of either human diploid cell rabies vaccine (HDCV) or purified chick embryo cell (PCEC) vaccine. Travelers should receive all three pre-exposure immunizations before travel. If three doses of rabies vaccine cannot be completed before travel, the traveler should not start the series.

Travelers who complete pre-exposure prophylaxis and are potentially exposed to the rabies virus should still seek additional medical care, as the pre-exposure prophylaxis does not eliminate the need for post-exposure prophylaxis. However, the pre-exposure vaccination may provide some amount of protection, especially if post-exposure prophylaxis must be delayed.[2]

Evaluation and Management of Bite Wounds

Post-exposure prophylaxis is needed only for bite wounds sustained in the countries listed in Table 118-4. Recommendations for post-exposure prophylaxis have been updated and provided by the ACIP.[12]

Table 118-4. Countries Reporting No Cases of Rabies During 2012[2]

Table 118-4 Countries Reporting No Cases of Rabies During 2012

Region[1]	Countries/Localities
Africa	Cape Verde, Mauritius, Réunion, São Tomé and Príncipe, and Seychelles
Americas	North: Bermuda, Saint Pierre and Miquelon Caribbean: Antigua and Barbuda, Aruba, The Bahamas, Barbados, Cayman Islands, Dominica, Guadeloupe, Jamaica, Martinique, Montserrat, Netherlands Antilles, Saint Kitts (Saint Christopher) and Nevis, Saint Lucia, Saint Martin, Saint Vincent and Grenadines, Turks and Caicos, and Virgin Islands (UK and U.S.)
Asia and the Middle East	Hong Kong, Japan, Kuwait, Malaysia (Sabah), Qatar, Singapore, Taiwan, United Arab Emirates
Europe[2]	Albania, Austria, Belgium, Corsica, Cyprus, Czech Republic, Denmark, Finland, France, Germany, Gibraltar, Greece, Hungary, Iceland, Ireland, Isle of Man, Liechtenstein, Luxembourg, Monaco, Netherlands, Norway (except Svalbard), Portugal, Slovakia, Slovenia, Spain(except Ceuta and Melilla), Sweden, Switzerland, and United Kingdom
Oceania[3]	Australia,[3]Cook Islands, Fiji, French Polynesia, Guam, Hawaii, Kiribati, Micronesia, New Caledonia, New Zealand, Northern Mariana Islands, Palau, Papua New Guinea, Samoa, and Vanuatu

[1]Global surveillance efforts and reporting standards differ dramatically, conditions may change rapidly because of animal translocation, and bat rabies may exist in some areas that are reportedly "free" of rabies in other mammals.

[2]Bat lyssaviruses have been reported throughout Europe, including areas that are reportedly free of rabies in other wild mammals.

[3]Most of Pacific Oceania is reportedly "rabies-free," with the exception of Australia, where lyssaviruses in bats have been reported, as well as fatal human rabies cases.

From Centers for Disease Control and Prevention. *Health Information for International Travel*, 2014. Washington, DC: U.S. Government Printing Office, 2014 (known as the Yellow Book).

Scheduling and Administration

In the pre-exposure setting, a 1.0-mL injection of HDCV or PCEC vaccine should be given intramuscularly (IM) in the deltoid on days 0, 7, and 21 or 28.

Reactions

Local reactions, including pain, erythema, swelling, or itching at the site of injection and mild systemic reactions, such as headache, myalgias, and nausea, are not uncommon. After booster injections with HDCV, about 6 percent of recipients develop urticaria, pruritus, and malaise.

Contraindications

Pregnancy is not a contraindication to use of rabies vaccine in the post-exposure setting. If pre-exposure immunization of persons who are immunocompromised is deemed essential, post-vaccination antibody titers should be checked.

TYPHOID FEVER

Disease

Typhoid fever is a severe, potentially life-threatening illness due to infection with *Salmonella typhi.*

Epidemiology

Approximately 22 million cases of typhoid fever occur worldwide each year, resulting in 200,000 deaths. About 400 cases of typhoid, primarily among travelers, occur annually in the United States.

The risk to travelers exists in the developing countries of Asia, Africa, and Latin America who have exposure to contaminated food or beverages. Persons visiting friends and relatives and who are less

likely to consume safe food and beverages may be particularly vulnerable.

Vaccine

Two vaccines are currently available in the United States:

- Oral live-attenuated vaccine (from the Ty21a strain of*S.entericaserotype Typhi*)
- Vi capsular polysaccharide vaccine (ViCPS) for IM use

The reported efficacy for these vaccines ranges from 50 to 80 percent. Travelers should be advised that the vaccine is not 100 percent effective and that they must use proper food and water precautions in addition to the vaccine to help prevent illness.[2]

Contraindications and Adverse Reactions

On a theoretical basis, vaccination during pregnancy should be avoided.

Table 118-5 Dosage and Schedule for Typhoid fever Vaccination

Vaccination	Age (Y)	Dose, Mode Of Administration	Number Of Doses	Dosing Interval	Boosting Interval
Oral, Live, Attenuated Ty21a Vaccine (Vivotif)[1]					
Live, Oral Vaccine (Ty21a)					
Primary series	≥ 6	1 capsule,[2]oral	4	48 hours	Not applicable
Booster	≥ 6	1 capsule,[2]oral	4	48 hours	Every 5 years
Vi Capsular Polysaccharide Vaccine					
Primary series	≥ 2	0.50 mL, intramuscular	1	Not applicable	Not applicable
Booster	≥ 2	0.50 mL, intramuscular	1	Not applicable	Every 2 years

[1]The vaccine must be kept refrigerated (35.6°F–46.4°F, 2°C–8°C).
[2]Administer with cool liquid no warmer than 98.6°F (37°C).
From Centers for Disease Control and Prevention. *Health Information for International Travel*, 2014. Washington, DC: U.S. Government Printing Office, 2014 (known as the Yellow Book).

Adverse reactions to Ty21a vaccine are rare and mainly consist of abdominal discomfort, nausea, vomiting, and rash. ViCPS vaccine is most often associated with headache and injection site reactions.[2]

Immunocompromised States

Avoid use of live, oral Ty21a vaccine in persons who are immunocompromised; instead, capsular polysaccharide vaccine should be used.

Special Considerations

Travelers who choose to vaccinate themselves via the live oral vaccine must be able to keep the tablets refrigerated during the duration of therapy. It is important to note that inactivated vaccines van be administered simultaneously or any time before or after the oral typhoid; however, other live-attenuated vaccines should either be given simultaneously, or a waiting period of 30 days is required, as the efficacy of live-attenuated vaccines may be affected if given sooner.[2]

The live, attenuated Ty21a vaccine should not be given to persons within 24 hours of taking antibiotics that can inhibit growth of the vaccine bacteria, thus reducing immunity. Immunoglobulin does not appear to cause such interference.

VACCINES ALSO INDICATED FOR HIGH-RISK POPULATIONS WITHIN THE UNITED STATES

HEPATITIS B

Hepatitis B is of low risk to most international travelers, except to persons engaging in higher-risk activities who will be visiting countries with moderate to high endemic rates of infection, which include countries in Asia, northern Canada, Greenland, and parts of South America. (See the CDC website and refer to the map on the National Center for Infectious Diseases Travelers' Health page for Hepatitis B for a graphical representation of these zones.) Persons visiting areas with intermediate to high prevalence of infection (> 2 percent) should receive a primary series of vaccine.[2]

INFLUENZA

The risk of influenza infection to the international traveler depends on the time of year and the countries visited. In tropical regions, influenza occurs throughout the year. In temperate regions of the southern hemisphere, the main period of risk is from April through September. Even during "off season" periods for influenza, travelers may be exposed if touring with large groups of visitors from other areas of the world where influenza is actively circulating.

Persons at high risk for influenza should be advised to receive the vaccine before travel if they did not receive the vaccine from the preceding fall-winter season and if they will travel:

- To the tropics at any time during the year
- With tourist groups from other areas of the world where influenza may be occurring
- To the southern hemisphere between April and September[2]

Because influenza vaccine may be difficult to locate during the summer in North America, persons at highest risk should speak with their physicians before travel. Three types of influenza vaccine are now available: inactivated vaccine given by IM injection, inactivated injection given by intradermal injection, and live-attenuated vaccine given by nasal spray. Vaccination is recommended for all individuals over 6 months of age; however, the live-attenuated vaccine is approved only for healthy, nonpregnant persons 2 to 49 years of age.

PNEUMOCOCCAL DISEASE

Physicians and other healthcare providers who provide pretravel counseling for persons at high risk for pneumococcal infection[13]who have not yet received vaccine should take the opportunity to advise

immunization prior to travel.

OTHER VACCINES

CHOLERA

Cholera risk is very low for travelers following standard tourist routes who observe basic recommendations regarding food and water safety. Moreover, at present, no country officially requires cholera vaccine prior to entry. However, local authorities in certain areas may nonetheless require documentation of vaccination against cholera. Where such circumstances are known to exist, it is advisable to write a letter of exemption from local requirements for cholera vaccination to avoid possible detainment at the border or the requirement for immediate vaccination.[2]

Production of the only cholera vaccine licensed in the United States has been discontinued by the manufacturer. New oral cholera vaccines are being developed that may provide a higher level of protection, but none has yet been approved by the U.S. Food and Drug Administration.[14]

PLAGUE

The risk posed by plague to international travelers is exceedingly small, and special protection is rarely indicated for persons staying in standard tourist accommodations. Generally, vaccination has been considered for persons likely to have exposure to wild rodents or similar animals in plague-epizootic areas and for persons who will reside or work in plague-endemic areas where it may be difficult to avoid either rodents or fleas. In enzootic regions, the risk of plague is highest in semiarid grassland or mountainous areas. Factors increasing the population size or migration of wild rodents increase the likelihood of human contact with plague. Rodent-infested areas should be avoided, and sick or dead rodents should not be handled. In enzootic areas, travelers may apply insect repellants to skin and repellants and insecticides to clothing and bedding.

Production of plague vaccine has been discontinued by the manufacturer. Consequently, travelers deemed to be at high risk for plague currently should be advised to consider short-term prophylaxis with tetracycline or doxycycline during periods of exposure. In place of tetracyclines, trimethoprim-sulfamethoxazole may be considered for use in children.[15]

SMALLPOX

Since the global eradication of smallpox was certified by WHO in 1980 and the disease was deleted from the International Health Regulations in 1982, smallpox vaccination should no longer be administered to international travelers unless a travel advisory is issued by the CDC. The last reported endemic case of smallpox occurred in Somalia in 1977, and the last reported laboratory-associated case was acquired in the United Kingdom in 1978.

PREGNANCY AND VACCINATIONS

Table 118-6 provides a comprehensive list of vaccinations and considerations of use during pregnancy.

SEEKING MEDICAL CARE ABROAD

Before taking any major journey to a foreign country, travelers should always be certain to know what expenses their health insurance will cover in the event of a medical emergency abroad. They should bring a copy of their health insurance ID card and a claim form, and they should be aware that even

the most comprehensive standard policy will not cover evacuation to the United States in case of medical emergency. Travelers looking for additional peace of mind should consider joining the nonprofit International Association for Medical Assistance to Travelers (IAMAT) (see Supplemental Resources). It can provide a reference source containing the names of Western-trained physicians who are located in most countries of the world and who may be called on in the event of a medical emergency for a preset fee. If further assistance is needed in finding emergency care, travelers can contact the American consulate in the host country. It is advisable for travelers to have these numbers, available through the U.S. Department of State's website, before departure (see Supplemental Resources).

Table 118-6 Considerations for Vaccination During Pregnancy

	Vaccine	Use During Pregnancy
Diphtheria-tetanus	Toxoid	If indicated, such as lack of primary series, or no booster within past 10 years
Diphtheria-tetanus-pertussis	Toxoid-acellular	Not contraindicated, but data on safety, immunogenicity, and outcomes of pregnancy are not available. Second or third trimester is preferred, if vaccine is indicated.
Hepatitis A	Inactivated virus	Data on safety in pregnancy are not available. Should weigh the theoretical risk of vaccination against the risk of disease. Consider immunoglobulin rather than vaccine.
Hepatitis B	Recombinant or plasma-derived	Recommended for women at risk of infection.
Immunoglobulins, pooled or hyperimmune	Immunoglobulin or specific globulin preparations	Administer if indicated for pre- or post-exposure. No known risk to fetus.
Influenza	Inactivated whole virus or subunit	All women who are pregnant during the flu season; women at high risk for pulmonary complications. Vaccination may occur in any trimester.
Japanese encephalitis	Inactivated virus	Data on safety in pregnancy are not available. Should weigh the theoretical risk of vaccination against the risk of disease.
Measles	Live-attenuated virus	Contraindicated; vaccination of susceptible women should be part of postpartum care.
Meningococcal meningitis	Conjugated	Data on safety in pregnancy are not available. Weigh theoretical vaccination risk against that of disease.
Mumps	Live-attenuated virus	Contraindicated; vaccination of susceptible women should be part of postpartum care.
Pneumococcal	Polysaccharide	Administer if indicated.
Polio, inactivated	Inactivated virus	Indicated for susceptible pregnant women traveling in endemic areas or in other high-risk situations.
Rabies	Inactivated virus	Administer if indicated.
Rubella	Live-attenuated virus	Contraindicated; vaccination of susceptible women should be part of postpartum care.
Typhoid (ViCPS)	Polysaccharide	If indicated for travel to endemic areas
Typhoid (Ty21a)	Live bacterial	Data on safety in pregnancy are not available.
Varicella	Live-attenuated virus	Contraindicated; vaccination of susceptible women should be considered postpartum.

Yellow fever	Live-attenuated virus	Postponement of travel preferred. May be used if exposure unavoidable.

Conclusions

Given the complexity of recommendations for immunizations, chemoprophylaxis, and other protective measures, travel medicine has evolved to become an area of specialized interest for many practitioners. It is essential that general information be individualized to account for the itinerary, medical history of the traveler, and the type of activities anticipated.

Although immunizations remain the central element of routine protection, a variety of medications and other strategies can be used to reduce the risk or ameliorate the effects of numerous disorders, including malaria, travelers' diarrhea, motion sickness, and altitude sickness. Those providing advice to travelers should be thoroughly grounded in the basics of the field by consulting comprehensive reviews such as the most recent edition of *Health Information for International Travel*. Because travel advisories are often issued rapidly in response to an evolving health threat abroad, practitioners need to be certain that they are aware of all updates provided through the CDC and employ the most current recommendations available to protect those they serve.

Future Trends

International travel medicine is increasingly looked on as an area of specialized practice. Those providing services to travelers need to be familiar with the full array of interventions available to ensure the health of persons traveling abroad. Certification in travel medicine is now available.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Emergency Management

Author(s): Terri Rebmann, PhD, RN, CIC
Associate Professor

Saint Louis University, School of Public Health--Institute for Biosecurity
St. Louis, MO

Published: October 3, 2014

Abstract

Many types of disasters may potentially affect healthcare, ranging from natural disasters to man-made events. Emergency management is the process by which an individual, facility, and/or community uses mitigation strategies to better prepare for, respond to, and recover from all types of disasters/emergencies and mass casualty events. To accomplish this, an all-hazards approach must be utilized. Emergency management is a multidepartmental, multiagency endeavor that requires coordination and communication among many groups to be most effective. It is essential that infection preventionists participate in all phases of the emergency management process to decrease the mental health impact, costs, morbidity, and mortality related to mass casualty incidents.

Key Concepts

• Disasters and mass casualty incidents may be the result of nature, emerging infections, or man-made events.

• Disasters and mass casualty incidents differ from other emergencies in their large scale and potential to result in mass casualties.

• Advance planning and practicing of emergency management plans are essential to an effective response.

• Preparing for and responding to mass casualty incidents requires communication and coordination among many organizations and individuals.

• Infection preventionists have a unique skill set that enables them to better prepare for and respond to mass casualty events.

• The basic principles of emergency management remain the same for all types of disasters. Only the response interventions vary to address the specific needs of the situation.

• Preparedness includes (1) development of an emergency management plan, (2) education of responding individuals/agencies on the plan, (3) practicing the plan, and (4) evaluating the facility or community's level of preparedness.

Background

Globally, the number of disasters and people affected by such events has increased in the recent past. The Haitian earthquake in January 2010 and the summer heat wave later that year in Russia resulted in over 278,500 deaths, a higher disaster-related mortality toll than any year in the last two decades.[1] In 2011, the earthquake, tsunami, and subsequent radiological event in Japan resulted in almost 30,000 deaths and costs of more than $366 billion.[1] Outbreaks of emerging infectious diseases and pandemics, such as the 2009 H1N1 influenza A pandemic, have sickened and killed hundreds of thousands of people around the world. The 2009 H1N1 pandemic alone resulted in between 151,700 and 575,400 deaths worldwide, and the mortality rate was more than 1 percent.[2] Recent disasters have illustrated the need for healthcare personnel (HCP), public health officials, and healthcare institutions to become better prepared to effectively respond to these events. Disasters and mass casualty incidents may be the result of nature, emerging infections, or man-made events. Regardless of the source, disasters pose potentially devastating threats to the health and well-being of the population.

Infection preventionists (IPs) have a vital role in maintaining the health of patients, visitors, and employees in their facility and the community. The unique skill set of IPs enables them to better prepare for and respond to different types of mass casualty incidents. As experts in the fields of surveillance and epidemiology, IPs are responsible for investigating outbreaks and initiating interventions to prevent the transmission of infections that occur within healthcare. Because the infectious disease impact of a mass casualty incident will vary depending on the nature of the event, IPs must be familiar with the potential consequences of different types of disasters and mass casualty incidents. However, though interventions will vary with different types of disasters, the general principles of surveillance and epidemiology remain the same.

Historically, the role of the IP in emergency management has centered more on disaster response than on mitigation, planning, or disaster recovery. This is primarily because most disasters, such as famine and earthquakes, do not involve a communicable disease component or have a large infectious disease impact.[3,4] Therefore, emergency management planning has long been considered a role of security, facilities management, and administration rather than infection prevention.[4] As a result of the increased threat of a biological event (bioterrorism, outbreak of an emerging infectious disease, or pandemic), a shift has occurred in emergency management. Infectious disease prevention, control, and epidemiology are being seen as a more critical component of emergency management. The role of IPs has broadened to include mass casualty event preparedness responsibilities in addition to response duties. It has become imperative for IPs to take a lead role in better preparing themselves, their facilities, and their communities for all types of mass casualty incidents. The role of IPs in emergency management has been outlined and IPs should become familiar with this role.[4]

Basic Principles

Disasters are one type of emergency. Disasters differ from other emergencies by the scope of the event; unlike most emergencies, disasters have the potential to result in mass casualties. Newer emergency management terminology sometimes uses the terms "mass casualty incident" and "mass casualty event" as a substitute for the term "disaster." These terms will be used interchangeably throughout the chapter. Large-scale events pose unique challenges to healthcare and public health. Although small emergencies may be managed by a handful of individuals or a single facility, a mass casualty event requires communication and coordination among many responding departments and agencies. This makes disaster preparedness more difficult. Advance planning and practicing emergency management plans are essential to an effective response.

There are many types of disasters that may potentially affect healthcare, and they can be divided into two categories by source: (1) those caused by natural forces, such as floods, earthquakes, hurricanes, and emerging infectious diseases; and (2) those resulting from intentional or unintentional man-made events, such as traditional, biological, chemical, nuclear, or radiological emergencies. Another way of categorizing mass casualty incidents is by the nature of the event in terms of whether or not it involves an infectious disease. Noninfectious disease disasters include all natural and man-made events that do not have an infectious agent as the source of the incident. Examples include hurricanes, floods, earthquakes, and all forms of terrorism except bioterrorism. Infectious disease disasters include all events that involve a biological agent/disease, such as a bioterrorism attack, a pandemic, or outbreak of an emerging infectious disease (see **120. Infectious Disease Disasters: Bioterrorism, Emerging Infections, and Pandemics**). The response will vary from incident to incident, because each mass casualty incident poses unique risks to communities and therefore requires situation-specific interventions. This is true even among disasters caused by the same force; no two earthquakes are alike, and the response to each will vary. However, the basic principles of emergency management remain the same for all types of mass casualty incidents. All disasters have potential infectious disease implications, but infectious disease disasters pose the greatest risk to communities in terms of disease transmission. IPs will be needed for planning for all types of disasters, but their involvement will be most critical for infectious disease disasters.

The potential consequences of a mass casualty event depend on many factors, including the community's social, economic, and baseline health status; the type and scope of incident; and the community's level of advance preparedness. Potential consequences of disasters are best mitigated and decreased by engaging in preparedness initiatives. These include the following: (1) developing an emergency management plan, (2) educating responding individuals/agencies about the plan, (3) practicing the plan, and (4) evaluating the facility or community's level of preparedness.

Emergency Management

Disasters should be planned for and responded to using the principles of emergency management. Emergency management is composed of four principles: mitigation, preparedness, response, and recovery.[5]

MITIGATION

Mitigation describes actions taken to decrease the potential impact of a situation. These include interventions to either prevent or reduce morbidity and mortality and ease the economic and social

impact of the event on the affected community. Mitigation strategies vary depending on the type of mass casualty incident. Mitigation interventions can range from new policies or laws related to mass casualty incident assistance funding for floods or hurricanes to new laws related to the use of smallpox vaccine for a potential bioterrorism attack. Mitigation is affected by national and international policies and the infrastructure of the public health system. A stronger public health infrastructure will ensure a more rapid and effective response, which in turn will decrease the negative impact of a disaster. Putting shutters on houses in areas at risk for hurricanes and elevating houses and appliances in flood plains are examples of mitigation interventions that can decrease the impact of a potential mass casualty incident.

PREPAREDNESS

Preparedness is both a phase and the measures taken during this time. As a phase, preparedness refers to the time before an emergency occurs (see the section on Phases of a Disaster). Preparedness measures are those taken before an event that better prepare an individual, facility, or community to respond to an emergency. These include such interventions as developing a facility emergency management plan and educating the workforce to implement such a plan. In addition, practicing and evaluating the emergency management plan helps ensure the best response to a true mass casualty incident.

RESPONSE

Like preparedness, response refers to both a phase and the activities implemented during this time. As a phase, response refers to the time immediately after an emergency is detected. Response activities include interventions undertaken in response to a known or suspected event. During the response phase, personal and facility emergency management plans are implemented. In large disasters, community, regional, and federal emergency management plans may also be implemented. The response will depend on a number of factors, including the type and scope of the mass casualty incident and how rapidly the event is identified. Each mass casualty event poses unique challenges and requires individualized interventions. However, basic infection prevention and epidemiological principles remain the same, regardless of the type and scope of the disaster.

RECOVERY

Recovery refers to both a phase and interventions implemented during this time period. As a phase, recovery refers to the period after the emergency has been declared over. During the recovery period, the facility or community implements interventions necessary to return to its predisaster baseline (i.e., recovery interventions). Recovery activities will include the following: (1) establish short- and long-term goals to return facility or community to pre-event baseline, (2) evaluate emergency management plan implementation and gaps identified during response, (3) determine potential solutions to identified gaps in emergency management plan, (4) update emergency management plan to reflect lessons learned, (5) educate staff on changes in emergency management plan, and (6) practice new emergency management plan. This will include replenishing stocks of medical equipment and supplies and returning to daily activities and routine reporting structures. Another important component of the recovery phase is responding to the mental health impact on the community, including dealing with patients with posttraumatic stress disorder (PTSD).

Although emergency management terminology is new for many IPs, these principles can be compared and applied to infection prevention nomenclature. Mitigation strategies are synonymous with control measures that affect morbidity and mortality. Preparedness is synonymous with primary prevention.

Secondary prevention interventions occur during the response phase. Lastly, the disaster recovery phase involves the implementation of tertiary prevention strategies.

It is vital that healthcare facilities and communities use an all-hazards approach to emergency management. This means that a facility or community emergency management plan must be able to accommodate all types of potential mass casualty incidents, from natural to man-made. In addition, the emergency management plan must address disasters that involve a communicable disease, such as an outbreak of an emerging infection or a bioterrorism attack using an infectious agent.

Emergency management is a multidepartmental, multiagency endeavor that requires coordination and communication among many groups to be most effective. It is essential that IPs participate in all aspects and phases of the emergency management process to decrease the mental health impact, costs, morbidity, and mortality related to mass casualty incidents.

PHASES OF A DISASTER

All disasters consist of four phases: (1) preparedness, (2) impact, (3) response, and (4) recovery (see Figure 119-1). The first phase, preparedness, refers to the time before a mass casualty incident occurs. During this phase, there is no immediate anticipation of disaster in the near future; the length of this phase is indefinite. In some mass casualty incidents, the preparedness phase may include a warning period, during which a disaster is anticipated. Warning phases vary in length, depending on the type of mass casualty event. This may mean a day or two warning for hurricanes, hours for floods, minutes for tornadoes, or no immediate warning for earthquakes or acts of terrorism.

Figure 119-1.

The four phases of a disaster. View Image

The second, or impact, phase includes the time while the actual mass casualty incident is occurring. This time period can vary from seconds for an earthquake to weeks for a flood. Activities undertaken during the impact phase vary, depending on the duration of this phase (seconds to weeks) and whether or not the event is immediately detected. In a covert bioterrorism attack, for instance, the release is likely to be detected only when patients become ill days to weeks after the event, making it impossible to implement interventions during the impact period. The third phase, response, begins at varying times, depending on the type of disaster and when the event is detected. In some disasters, such as a flood or hurricane, the response will most likely begin in conjunction with the impact phase. In other mass casualty incidents, such as a bombing or earthquake, the response phase will begin immediately after the impact. It is also possible for the response phase to begin long after the impact is over. Again, an example is a covert bioterrorism attack using an agent with a prolonged incubation period, such as smallpox. In this situation, the impact phase of the event (the release of aerosolized *Variola*virus) would end almost 2 weeks (i.e., the incubation period of smallpox) before the event is likely to be detected.

Regardless of when the response phase begins, it consists of interventions necessary to cope with the immediate effects of the disaster. In most mass casualty incidents, more injuries occur in the response phase, during rescue and cleanup efforts, than in the impact phase.[6]

The fourth and final phase of a disaster is the recovery period, which begins after the mass casualty incident has been officially declared over and no additional victims are likely to be rescued. In some disasters, the switch from response to recovery may be clearly delineated. For example, for most collapsed structure disasters, recovery efforts begin around 72 hours after the impact because it is rare

for victims to survive and be rescued after that point. In other disasters, recovery activities may begin during the response phase, without a clearly defined message that the facility or community has completed the response.

Recovery period interventions include those necessary for rebuilding the facility and community in terms of physical, psychological, and economic needs. The recovery period ends when life has "gotten back to normal," even if life is not the same as before.

INFECTIOUS DISEASE IMPLICATIONS OF DISASTERS AND MASS CASUALTY EVENTS

Communicable disease outbreaks are widely feared after disasters. Studies that examine the epidemiological impact of communicable diseases following mass casualty incidents find that the impact varies, depending on the situation. Studies examining acute-onset natural disasters, such as earthquakes or hurricanes, indicate that the risk of an infectious disease outbreak related to this type of event is small.[7,8,9]Outbreaks that occur after natural disasters often result from population displacement, such as overcrowding in community shelters, and lack of clean water or sanitation.[8]In developed countries, infectious disease outbreaks following a disaster are unusual; if they do occur, they usually involve skin, gastrointestinal, or respiratory infections.[7]Examples of this include the norovirus outbreak in a community shelter during Hurricane Katrina[7]and the doubling of infectious diseases (namely pneumonia and skin infections, including tetanus) among hospitalized patients following the 2011 Great East Japan Earthquake and tsunami.[10]In underdeveloped countries, infectious disease outbreaks following disasters are more common and are usually related to endemic pathogens, zoonotic diseases, and foodborne illness.[9]Zoonotic illnesses and vectorborne diseases increase after natural disasters due to wild and domesticated animal displacement that occurs in conjunction with human displacement, and because vector control measures may be temporarily halted.[9]Outbreaks of Hepatitis A, cholera, typhoid fever, and diarrheal illness have all been reported after natural disasters and are largely due to poor sanitation, improper food handling, and lack of healthcare access,[7]though rainfall and other environmental factors may also play a role.[11]One of the largest infectious disease outbreaks ever associated with a natural disaster occurred after the 2010 Haitian earthquake. Almost 1 year after the earthquake, an outbreak of cholera occurred in Haiti, with devastating outcomes. That outbreak accounted for over half of all cholera deaths in 2010 and was associated with more than 600,000 cases of cholera and over 7,000 deaths.[12]

Although there is a pervasive fear about potential infectious disease outbreaks caused by exposure to disaster victims' dead bodies, there is no evidence that this results in epidemics.[8]Exceptions to this would be outbreaks of cholera, viral hemorrhagic fevers, or smallpox, any of which could put people at risk from disease from exposure to victims' dead bodies if precautions are not taken.[8]Following any type of mass casualty incident, bodies of dead humans or animals should be handled using appropriate infection prevention precautions and personal protective equipment (PPE) to prevent infection transmission.[8]

Infectious disease disasters, such as a bioterrorism attack, outbreak of an emerging infectious disease, or pandemic, have the greatest potential for causing infection-related morbidity and mortality of any type

of mass casualty event (see **120. Infectious Disease Disasters: Bioterrorism, Emerging Infections, and Pandemics**).

EMERGENCY MANAGEMENT PREPAREDNESS

Preparedness is not a state of being perfectly prepared to respond to any type of mass casualty incident because this can never be achieved.[13] The goal is to become incrementally better prepared to respond to a disaster. Preparedness is the process of becoming better prepared to effectively recognize and respond to a mass casualty incident. This process consists of pursuing emergency management education, gaining knowledge on emergency management, planning and practicing response behaviors, and evaluating your level of preparedness.

The first step in the preparedness process is gaining knowledge through pursuit of education on emergency management. Educational topics include the following: (1) how to develop an emergency management plan, (2) what to include in an emergency management plan, (3) individuals/groups to include in the planning process, (4) how to conduct a facility assessment, (5) resource assessment, (6) designing and implementing an exercise or practice program, and (7) how to evaluate the level of preparedness of an individual, facility, or community. In addition, some disaster-specific information is required, such as information on floods, hurricanes, earthquakes, chemical and biological terrorism attacks, emerging infectious diseases, and pandemics.

EMERGENCY MANAGEMENT PLANS

One of the most critical elements of emergency management is the development of a comprehensive emergency management plan. There are three types of emergency management plans: (1) personal plan, (2) facility plan, and (3) community plan.[14]

Personal/Family Emergency Management Plan

A personal/family emergency management plan is designed for an individual's personal use. It should include provisions for backup care for children or adults for which you are responsible in the event that you are called in to work for an emergency during traditional nonwork hours. Your personal plan should also include a supply of food and water in case you and/or your family are trapped in your home, such as after an earthquake. Other components of a personal plan include having pet care, an out-of-state contact for your family, stores of medical equipment/supplies and PPE, and transportation during nontraditional working hours.[15]

Review your family emergency management plan with every member of your family, with special emphasis on what is to be done if the family is separated. This is an infection prevention issue because IPs will not be able to work effectively if they are worried about their family and unable to communicate with them. Recent studies indicate that many healthcare providers, including IPs, do not have a personal emergency management plan.[16,17] A 2007 study reported that only half of all IPs have a personal emergency management plan.[16] This can hinder emergency management if staff is unable to work during a mass casualty incident. It is the responsibility of all healthcare staff to have a personal plan that will allow them to work during a disaster.

Healthcare Facility Emergency Management Plan

A facility emergency management plan is a plan a healthcare facility would implement during or after a mass casualty event. Facility emergency management plan development is a multidiscipline and

multiagency collaborative process; an individual working alone should not undertake it. It is best if a planning committee develops the facility emergency management plan. This committee should consist of the following members: (1) IPs, (2) hospital epidemiologist or infectious disease physician/representative, (3) nursing administration, (4) security, (5) housekeeping, (6) central supply, (7) food and nutrition, (8) hospital administration, (9) occupational health, (10) environmental health, (11) legal counsel/risk management, (12) public relations/public information officer, (13) medical staff, (14) human resources, (15) physical therapy, (16) emergency department, (17) respiratory therapy, (18) local law enforcement, (19) local FBI, (20) local emergency management services, and (21) public health representative.[18]In larger facilities, there may be many additional members and in smaller facilities there may be fewer.

In the event of a mass casualty incident, these responding groups and agencies will need to work together; it is best to have these partnerships developed before such an event occurs to ensure a better outcome. A facility emergency management plan must be a written plan that addresses issues including the following: (1) resource management (both staff and supplies), (2) communication systems/methods, (3) reporting structure, and (4) patient management. Tools are available to assist in the development of a written healthcare facility emergency management plan.[3,18,19,20]Although these planning tools are specific to infectious disease disaster preparedness, they can serve as the foundation for an all-hazards emergency management plan. IPs should use these tools to get involved with emergency management at the facility (i.e., hospital or healthcare facility) level.

Community Emergency Management Plan

A community emergency management plan is a plan a community would implement during or after a mass casualty incident. Community emergency management plans are a collaborative effort among traditional first responders (law enforcement, fire protection, and emergency medical services), healthcare facilities, public health officials, and other response agencies within a community. Although it was previously thought that IPs would not be needed to assist in emergency management at the community level, new evidence indicates that it is vital that IPs be involved in this activity.[4]IPs' input will be required for setting up and running alternate care sites,[21]points of dispensing (POD),[22]and community evacuation shelters,[23]and for communicating infection prevention messages to the general public.

HEALTHCARE FACILITY ASSESSMENT

Facility assessment is the first step in developing a healthcare facility emergency management plan. A hazard and vulnerability assessment (HVA) should be conducted in conjunction with facility assessment. HVA tools examine region-specific hazards (flooding in floodplain areas, earthquakes in southern California, etc.). In addition, these tools assess a facility's or community's vulnerability to certain types of mass casualty events. One example is identifying hospitals that are located on a fault line and may be at an increased risk from an earthquake. An example of an HVA is one developed by Kaiser Foundation Health Plan, Inc.[24]HVA tools use a systematic approach to conducting an HVA (see Figure 119-2). The user scores the facility on such factors as the probability of a specific mass casualty incident occurring, as well as the severity or potential impact of the event if such a disaster occurred. Combined, these quantitative measures provide the facility with a relative threat/risk score. The risk score aids facilities in determining which potential disasters are highest priority for emergency management planning. An all-hazards approach must be used in emergency management so that facilities are prepared for all types of mass casualty incidents, but facilities should focus their efforts on the highest priority threats.

Performing a facility assessment related to infection prevention issues is a time-consuming, multidepartmental endeavor and should not be undertaken alone.[18] It is also important to note that The Joint Commission (TJC) has standards that address hospital emergency management, including standards that address infection prevention during disasters. TJC standards are updated fairly regularly; IPs should verify existing standards when assessing hospital emergency management plans or developing new protocols. Hospitals must address TJC standards in their emergency management plan if they wish to be accredited.

HAZARD AND VULNERABILITY ASSESSMENT TOOL
NATURALLY OCCURRING EVENTS

Figure 119-2.

HVA tool for naturally occurring

View Image

After a disaster strikes, additional healthcare facility assessments will be necessary. The evaluation of the building for structural safety is not an infection prevention issue, but evaluation for function is. Assessing the availability of a functional sewer system is an urgent priority (see the Sewage and Sanitation section), as is checking for water infiltration that can lead to mold. Dust may also pose a risk after a mass casualty incident. Because this dust may contain *Aspergillus*, the emergency management plan should specify what kind of protection is available for patients at risk for aspergillosis, procedures for reducing dust inside the facility, and policies for minimizing patient exposure to dust in and around the healthcare complex. After a natural disaster, facilities should assess that the plumbing and water systems are intact and that clean water is available before using the water for ingestion, cooking, cleaning, or disinfection of instruments.

During recovery, the facility will need to assess needs to return the facility to normal or baseline. This includes an assessment of the facility's emergency management plan to determine gaps that need to be addressed before another mass casualty event occurs. Facility resource assessment will remain critical; replacement of lost resources is a central component of the recovery phase. A facility may have to restock PPE, medications, and other medical supplies. They may also need to deal with a loss of staff members who fell victim to the mass casualty incident, as HCP often make up a large portion of a community's population.

COMMUNITY ASSESSMENT

It is important for communities to determine their risks and vulnerabilities. Predisaster community assessments are generally broad vulnerability and risk assessments of the community. After disaster strikes, a more focused assessment must be performed to determine who in the community is at risk. For instance, predisaster, it may be determined that floods are a risk in certain subsets of the community; however, once a flood occurs, it is imperative to rapidly assess exactly which areas of the community are affected. The information gathered during the response is usually "quick and dirty" and is utilized to identify immediate interventions required to handle the response. Data collected often include logistical data and information specific to the mass casualty incident, such as a list of people or families that live or work in a flooded area so that tetanus vaccination needs can be determined.

Assessments performed during recovery include those needed to assess the community's needs to return to normal or baseline. This includes an assessment of the community's resources and emergency management plan. In addition to replacing lost resources, the community will have to address the mental health and spiritual consequences of a large mass casualty event.

SURGE CAPACITY

The ability of a healthcare facility to handle an influx of patients requiring medical care is known as surge capacity. Most hospitals and healthcare facilities function at maximum capacity on a routine basis and have very little surge capacity. Despite this, TJC requires hospitals to establish and improve surge capacity to meet the community's needs during a mass casualty incident. There are currently no quantitative standards in the United States regarding how much surge capacity a hospital must have. In Israel, hospitals are required to have the ability to expand to accommodate a surge of at least 20 percent over standard operating procedure.[25,26]

Surge capacity is more than simply increasing the number of patient beds. In addition to beds, surge capability resources must be available to staff those beds and manage the increased patient loads. This involves having the personnel, facilities (i.e., negative pressure rooms/areas, morgue space, laboratory processing, etc.), medical equipment/supplies (ventilators, PPE, hand hygiene products, etc.), and pharmaceuticals to care for the patients. Facilities need to factor in all surge capacity components as part of emergency management.

Researchers have examined a variety of aspects of U.S. hospital surge capacity preparedness. Although methods have been identified to simply increase bed availability by 10 to 20 percent,[25] this does not allow for a surge of patients requiring intensive care. Infectious disease disasters and terrorist events will likely result in an increased need for highly specialized treatment in intensive care beds. This can include the need for more burn and trauma intensive care beds during an incendiary event, such as a terrorist bombing, or intensive care areas that can accommodate patients needing mechanical ventilation for biological events. Even natural disasters require more resources than simply having additional beds available within the facility.

Studies indicate that most facilities fall short on having the resources and infrastructure needed to manage all aspects of patient care, especially for events that last longer than a few days.[16,27] Examples include an identified lack of ventilators, antibiotics or antiviral medications, respiratory protection (N95 respirators), negative pressure rooms/areas, laboratory support/supplies, and linens.[16,27,28] In addition, the national nursing shortage and failure to cross-train HCP limits hospitals' ability to care for an influx of severely ill patients, such as those requiring ventilatory support.[16] Some hospitals even lack 24/7 infection prevention coverage, which would make responding to an infectious disease disaster very challenging.[16]

Recent research indicates that U.S. hospitals,[16,26] home health agencies,[29] businesses,[30] and schools[31] are not as prepared as possible for mass casualty incidents of any type, especially those involving mass casualties or an infectious disease. Intensive care beds, HCP, PPE, and medical supplies are not available in sufficient numbers to address the unique needs of many mass casualty events. Even after basic surge capacity issues are better addressed, research is needed to determine how to maintain surge care for longer periods of time. Although natural disasters may be short-term events, mass casualty incidents involving a biological agent could last weeks to months. Even natural disasters can

require long-term surge capacity, as was evidenced by Hurricane Katrina in 2005, the Haiti earthquake in 2010, and the Great East Japan Earthquake in 2011.

ASSESSING FOR SURGE CAPACITY

The availability and backup supplies of both staff and equipment should be assessed. Most healthcare facilities keep less than 3 days' stock of commonly used medical supplies. In the event of a mass casualty event with an accompanying large influx of patients, daily stocks of supplies will quickly be depleted. This may include PPE such as gloves, masks, ventilators, and linens. It is best to plan for this increased need for equipment prior to an event. Memoranda of agreement between local and regional facilities and companies help ensure that equipment is available rapidly when needed. Healthcare facilities should consider forming or joining a hospital disaster alliance.

Staffing will be a major issue following a mass casualty event. More staff will be needed to address the patient management issues, such as triage, patient care, and dealing with the "worried well." It is best to have written plans for obtaining backup staff for extra shifts during a mass casualty incident. A recent study indicated that U.S. hospitals do not have sufficient staff to handle a surge of patients.[16]A 2007 study reported that only half of all U.S. hospitals have a plan for obtaining additional staff during disasters.[16]Staff will require frequent rest breaks, which will also need to be addressed in the plan.

Whenever possible, it is best to have memoranda of agreement with healthcare facilities and staffing agencies or groups to ensure more rapid deployment of backup staff when needed. Another option for increasing staff surge capacity is to offer incentives to encourage employees to report to work during a mass casualty incident. Although staff indicate that incentives are one way to entice them to work during a mass casualty event, less than half of all hospitals in a 2007 study reported that they plan to offer incentives to employees.[16]Of the hospitals that did report including employee incentives in their emergency management plan, the most frequent incentives included free child or adult family member care, temporary housing and subsistence, and priority access to anti-infective therapy or vaccination.[16]

The facility emergency management plan should identify the cost of disaster-related supplies and services as completely as possible. This will facilitate requests for emergency assistance from the Federal Emergency Management Agency (FEMA). Costs of preparation should also be tracked and documented.

ALTERNATE CARE SITES

Alternate care sites are temporary locations for providing medical services during a mass casualty incident. An alternate care site may consist of a hotel, closed hospital, mobile field hospital, nursing home, converted warehouse, school, stadium/sports arena, convention center, fairground, meeting hall, gymnasium, health club, or any building or space that is adapted for providing medical care.[21,32]

Alternate care sites can even include the use of large tented areas, such as those used during past smallpox outbreaks.[21]Alternate care sites are used to decrease patient flow and congestion problems at hospitals during the busiest times of the mass casualty event, allowing the hospital to manage only the most severely ill patients. The level of medical treatment provided at alternate care sites will vary by the community and the size/scope of the event. Because medical care will be administered at these sites, the risk of infection transmission exists. Therefore, it is essential that IPs be involved in developing or implementing an infection prevention program for alternate care sites, regardless of whether the site is under the umbrella of the healthcare facility or is part of the community.[21]This will necessitate IP involvement in emergency management at the community level.

EVACUATION

Some mass casualty incidents will require building and/or area evacuation. This is most likely to be necessary during disasters that cause building structural damage, such as earthquakes, tornados, bombings, or explosions. For example, 11 hospitals had to be evacuated because they were floodbound, had electrical failures, or loss of water after Hurricane Katrina hit,[33] and one hospital was completely destroyed during the 2011 tornado that hit Joplin, Missouri.[34] In addition, the majority of the hospitals and healthcare facilities in New Orleans were destroyed or unable to function after Hurricane Katrina, necessitating the evacuation of tens of thousands of individuals from their homes and hospitals.[35] Safe relocation of patients, worried well, family, and visitors must be planned in advance, including transfer and patient placement protocols for potentially contagious patients.

COMMUNITY EVACUATION SHELTERS

Some disasters may require the displacement of individuals from their homes into community evacuation shelters. These shelters can house hundreds or thousands of individuals in overcrowded conditions, often with limited access to traditional sanitation, food, and water control.[23] A lack of resources for cleaning and hand hygiene supplies can contribute to disease spread in shelters. In addition, it is likely that individuals requiring community sheltering may be at increased risk for infection due to underlying illness that prevented their evacuation from the affected area.[23] All of these conditions can contribute to disease spread and infectious disease outbreaks among sheltered individuals.[23] Past experience with natural mass casualty incidents indicates that the most likely infectious diseases/conditions to occur in community evacuation shelters include skin/dermatological, gastrointestinal, and respiratory infections.[7] IP involvement is needed at the community level to assist in setting up an infection prevention program for evacuation shelters. Guidelines for preventing infectious disease transmission in shelters during disasters have been developed by the Association for Professionals in Infection Control and Epidemiology (APIC).[23]

REPORTING DISASTERS

Healthcare facilities need procedures for reporting mass casualty incidents both internally and externally. Internally, all hospital departments will require notification of a disaster. If the mass casualty event involves an infectious disease, rapid notification of the infection prevention and/or hospital epidemiology department is vital. Externally, local and regional responding agencies must be notified of disasters. Examples of responding agencies include public health, emergency medical services, law enforcement, and emergency managers. Procedures for internal and external notification/reporting should be incorporated into the healthcare facility's emergency management plan.

COMMUNICABLE DISEASE REPORTING

Routine communicable disease reporting will need to continue during a mass casualty incident. In addition, certain communicable diseases may need to be reported in a timely manner during a disaster because of the risk of secondary spread. For example, chickenpox or measles that occurs in a disaster-affected population should be reported to the public health department right away, as these diseases can result in rapid spread in crowded surroundings such as community evacuation shelters.

RESOURCE MANAGEMENT

Resource management must be well planned to ensure the best allocation of resources during a mass casualty incident. This means planning for obtaining, allocating, and distributing resources during a mass casualty event. Resources include both staff and supplies necessary to effectively recognize and respond to all types of mass casualty incidents. Does the facility have enough beds to accommodate a large surge in patients? Is there a large enough qualified staff to care for these patients? Are there adequate stocks of medical supplies, equipment, and pharmaceuticals to care for a large increase of patients? These questions must be addressed during facility emergency management planning to ensure the best response.

Resource assessment should take place as part of facility assessment. The following are items that must be assessed: (1) on-hand functional equipment, (2) sources and quantities of backup equipment, (3) on-hand pharmaceutical supplies, (4) sources and quantities of backup pharmaceutical supplies, (5) amount of available staff, (6) source and size of backup staff, and (7) surge capacity of the facility. Each event will pose unique challenges in terms of resources required. Some disasters, such as an earthquake or flood, will require physical plant resource needs, such as safe shelter, food, and water. Other mass casualty incidents may require different or additional resource needs, such as PPE, medications, and vaccines after a bioterrorism attack or pandemic (see **120. Infectious Disease Disasters: Bioterrorism, Emerging Infections, and Pandemics**for detailed information on infectious disease emergency management).

It is best to take an all-hazards approach to emergency management. The type of disaster that will occur cannot be predicted; therefore, a broad approach will help ensure a better response to any mass casualty incident. The emergency management plan should address the possibility of prolonged loss of electricity, potable water, or another essential utility. How available resources will be assessed and maintained on an ongoing basis should be specified.

During the response phase of a mass casualty event, resources will quickly become depleted. Utilizing prearranged memoranda of agreement between healthcare facilities and vendors should help alleviate scrambling for resources during the mass casualty incident. As the disaster response progresses, constant evaluation of resource stocks must be performed so that gaps may be quickly identified and backup stocks may be obtained. IPs may have to assess available antibiotic prophylaxis or vaccination doses or amounts of PPE for isolation. They will also have to assess the amount of available drinking water and clean water for handwashing, hand hygiene products, bathing, linen management, equipment sterilization, dietary maintenance, dialysis, and toilet facilities. Another critical aspect of resource assessment during a mass casualty incident response is the assessing availability of sewage facilities to safely dispose of human waste.

CRISIS STANDARDS OF CARE

Despite the best planning efforts, resources may become completely depleted following a mass casualty incident. If this occurs, supplies may need to be rationed based on priority. Making prioritization decisions in advance of a mass casualty event is known as developing crisis standards of care. These prioritization algorithms are only to be used in times of crisis or disaster when routine standards of care cannot be met. For instance, decisions will need to be made about which patients will receive limited numbers of ventilators or other medical equipment. Protective equipment for staff may also need to be rationed. For example, staff who perform aerosolizing procedures that put them at high risk from airborne-spread diseases should be a top priority for respiratory protection in the form of N95 respirators or their equivalent. Lower-risk areas may need to reuse respirators, cohort infected patients, and/or use a lower level of respiratory protection. If sterilization of reusable equipment is limited, consider high-level disinfection when acceptable. Other supplies may need to be rationed or prioritized

as well. Department managers should be involved in determining what amounts of supplies essential to their operation should be kept on hand. Keep in mind that operations may be heavier than usual, and that a supply adequate for three normal days may not be adequate during a mass casualty event.

Developing crisis standards of care for allocating scarce resources is an important component of emergency management and it has infectious disease implications. Deciding who receives limited doses of anti-infective therapy or vaccination can contribute to disease transmission or control. This is also true for PPE. Priorities must be determined before a mass casualty incident strikes, and procedures for safely reusing or allocating scarce PPE must be written into the facility emergency management plan. An example of existing guidance on allocating scarce resources is the APIC position paper, *Extending the Use and/or Reusing Respiratory Protection in Healthcare Settings during Disasters*.[36]

PATIENT MANAGEMENT

Patient management is the largest component of disaster response and as such is an essential facet of emergency management. Mass casualty events pose unique challenges to healthcare facilities. How will the facility juggle a large number of acutely ill patients and deal with an influx of the worried well? It will not be business as usual. Rapid triage and health assessment will be critical to decreasing morbidity and mortality. In addition, infection prevention precautions may need to be implemented in the event of a mass casualty incident involving an infectious agent. Healthcare facility emergency management plans must address patient surge, including having procedures for managing potentially contagious patients.

Triage will be an essential component of patient management. One potential danger is that the hospital emergency department can be overrun following a mass casualty incident, causing chaos that complicates patient care. One option is to set up off-site triage areas, such as alternate care sites.[32]

Severely ill patients can then be transported to the hospital and less critical patients can remain at the off-site center to receive minimal care until hospital beds become available or when the patient's status becomes more critical. Off-site triage areas are recommended for handling and housing the worried well. This allows the hospital to maintain beds, staff, and supplies for the most critically ill patients. It also keeps transportation routes open both within and to the hospital to allow better flow of critically ill patients, medical supplies, and staff.

Another concern will be where to physically locate family members while patients are being triaged and treated. If the event involves an infectious disease scenario (such as a bioterrorism attack, outbreak of an emerging infectious disease, or a pandemic), arrangements will need to be made to identify potentially contagious individuals and separate them from others. These questions are best addressed during facility emergency management planning.

Two of the first steps in increasing bed surge capacity to handle the influx of patients is to empty the emergency department and discharge as many inpatients as possible to make way for incoming patients.[29]Patients' health status will need to be assessed to determine who can safely be discharged to home and who will require ongoing care at an alternate care site, long-term care, or home care. Patient discharge decision-making must take the patient's need for isolation into account. Some healthcare settings cannot accommodate a potentially contagious patient; this may limit patient discharge options and slow mass casualty incident response. During mass casualty events, such as a pandemic, all healthcare service providers will be swamped, which will make patient discharge a challenge. Hospitals should work with nonacute care agencies as part of disaster preparedness to ensure that rapid and effective patient discharge can occur during a mass casualty incident. Protocols and procedures for rapid discharge need to be arranged in advance.

Nonessential services will likely be temporarily ceased to divert resources to mass casualty incident patient management. This will include the cessation of nonemergency surgeries and other nonessential services. Facility emergency management plans should outline procedures for how essential services, such as obstetrical, emergency, dialysis, and outpatient services will be maintained. Patient transfer to other facilities may be needed; however, in mass casualty events, all local facilities may be overwhelmed. Transfer to more distant facilities may be necessary, though this may not be an option during a pandemic when all areas of the United States may be affected.

INFECTION PREVENTION PRIORITIES COMMON TO VARIOUS DISASTERS

Early Detection and Surveillance

Rapid detection of a disaster is crucial to a successful response. For all mass casualty incidents, the sooner the incident and at-risk patients are identified, the lower the likely morbidity, mortality, and cost. Planning for early detection of most mass casualty events is not necessary. For all natural disasters and even traditional or chemical terrorism, there are immediate, obvious signs that something unusual has happened, ranging from damaged buildings in an earthquake to a huge influx of patients immediately after a chemical attack. Early detection strategies are necessary for infectious disease disasters, on the other hand, because these events may be more difficult to detect, such as a covert release of an aerosolized agent. For information on syndromic surveillance and early detection of infectious disease disasters, see **120. Infectious Disease Disasters: Bioterrorism, Emerging Infections, and Pandemics**.

Surveillance

Surveillance after a mass casualty incident will likely be critical to decreasing costs, morbidity, and mortality associated with a disaster, depending on the type of event that occurred. This is especially true in the case of an infectious disease disaster, after which identification of new cases will be essential to save lives.

Infection prevention surveillance during mass casualty events must be maintained in a practical, feasible manner, even though the IP will probably be assigned to disaster-related duties.[4] Problems specific to the disaster must be detected, assessed, and acted on in a timely manner. Problems existing before the mass casualty incident must continue to be monitored—for example, an outbreak of methicillin-resistant *Staphylococcus aureus* (MRSA) that began before the disaster.

Disaster surveillance is based on the same principles as traditional surveillance but may require a more "quick and dirty" approach due to the urgency of the situation. Active surveillance initiated as part of mass casualty incident response is considered sentinel surveillance, and the primary goal is to quickly identify new cases. Surveillance programs implemented in response to a disaster are generally short term and end when the crisis ends or shortly thereafter. This is in contrast to ongoing public health and hospital-based surveillance programs such as bloodstream infection surveillance or tuberculosis (TB) monitoring. It will also be important to conduct community-based surveillance for infections following a mass casualty event. This will include having surveillance systems in place in alternate care sites and community evacuation shelters.[21,23]

Collecting and communicating credible surveillance data during a mass casualty incident provides the best methods for stopping rumors and for focusing attention on real health problems. It must be decided who is to collect, analyze, and report the data; what is to be collected; and for how long. This

information should be outlined in the facility emergency management plan (see **11. Surveillance**for more information).

Surveillance during the recovery period will most likely consist of a return to routine surveillance activities. In some cases, facilities may choose to continue surveillance for indicators begun as part of sentinel surveillance. For instance, during recovery from a bioterrorism attack, facilities may choose to continue active surveillance for the causative agent disease (such as pneumonic plague or inhalational anthrax) until they are certain the outbreak is over. Ongoing active surveillance will most likely be needed after infectious disease disasters in order to continue to identify new cases.

In addition, facilities also need to decide if new surveillance indicators are necessary. After recovering from a bioterrorism attack using anthrax, some facilities may choose to initiate a new syndromic surveillance program to quickly identify a potential future infectious disease disaster using any of a number of potential agents/diseases. Obviously, this would be resource intensive and would require a joint decision between administration and infection prevention.

Some facilities may use the findings of the epidemiological investigation to determine which aspects of surveillance should be maintained or initiated. Epidemiology during the response period focuses only on the immediate needs related to the mass casualty event. Once the crisis is over, a more in-depth investigation can be performed, focusing on risk factors, groups most affected, route of transmission, interventions that worked or did not work, and so on. The results of the epidemiological investigation must be disseminated throughout the facility and public. Publication in a peer-reviewed scientific journal should also be considered to share the results and lessons learned with a wider audience.

Epidemiological Outbreak Investigation During Disaster Response and Recovery

Few mass casualty incidents require a large-scale infectious disease epidemiological investigation, but almost every disaster requires some form of investigation to identify those affected and track patient follow-up. Each mass casualty event is unique and will pose distinct differences in the investigation. Floods, hurricanes, and earthquakes will usually not require an infectious disease epidemiological investigation, though they may if respiratory, foodborne, or waterborne illnesses occur. An example of this was the extensive epidemiological investigation of the cholera outbreak following the 2010 earthquake in Haiti.[12]Infectious disease disasters, on the other hand, will likely require an extensive epidemiological investigation. In this situation, rapid identification of exposed individuals and initiation of prophylactic therapy or vaccination is essential to decreasing morbidity and mortality.

An outbreak investigation would be warranted for any mass casualty incident that involves a communicable disease or one in which epidemiological information needs to be collected and analyzed, such as risk factor and outcome data. Typically, the epidemiology performed during disaster response is limited. The response phase is generally relatively short, and there is not sufficient time to establish and implement an epidemiological investigation (this occurs more frequently during the recovery phase). This is not true for all mass casualty events; infectious disease disasters are exceptions. For infectious disease disasters, the epidemiological investigation will be crucial to halting the outbreak.

Infection Prevention and Control Coverage

It is vital to maintain around-the-clock infection prevention coverage during a mass casualty incident, even if the facility's IPs will also have disaster-related duties to perform. Research indicates that some U.S. hospitals currently lack around-the-clock infection prevention coverage; this gap needs to be addressed before a mass casualty event occurs.[16]Infection prevention coverage in nonhospital settings (such as alternate care sites and community evacuation shelters) may need to be assigned to an

infection prevention designee. If this is to occur, these designees require education and training on how to implement and evaluate an infection prevention program in these settings. Infection prevention coverage in community-based nonhospital settings needs to be coordinated with community emergency managers/planners and/or public health officials.

Hand Hygiene

Hand hygiene remains one of the most essential infection prevention procedures following a mass casualty incident. Hand hygiene must be available even if tap water supplies are disrupted and/or hand hygiene products become depleted.

Healthcare facilities should maintain a stockpile of hand hygiene products, including soap and alcohol-based hand rub (ABHR) products, or have a memorandum of agreement for obtaining additional supplies during a mass casualty event. In addition, access to clean water for hand washing should be a priority (see **27. Hand Hygiene**).

Patient Placement and Isolation

Patient placement and isolation procedures are generally covered in a healthcare facility's routine policies. However, mass casualty incidents may prevent facilities from implementing routine standards such as placement in a private room for isolation. Healthcare facilities should outline protocols for cohorting potentially contagious patients as part of disaster planning. In addition, healthcare facilities need protocols to ensure that airborne infection isolation precautions can still be implemented during mass casualty events. Airborne infection isolation for patients with TB or other diseases spread by airborne droplet nuclei must be maintained. The emergency management plan should state how this would be done, including having a plan for short-term and long-term negative pressure surge capacity.[18,37] Temporary negative pressure for a room or area can be established during a mass casualty incident or patients can be transported to another facility to increase negative pressure surge capacity.[37]

Ventilation systems can be evaluated while on emergency power. HCP should watch for an increase in cases of TB or other airborne spread diseases in the subsequent months, as these may be related to the mass casualty event (crowding in community evacuation shelters). Treatment of TB patients in ambulatory care or directly observed therapy programs must be maintained.

Quarantine

Quarantine is another potential component of emergency management. It involves restricting individuals' movement as a means of preventing infection spread. Quarantine differs from isolation is that it restricts the movement of individuals who have a known or suspected exposure to an infectious disease or contagious individual but who are not yet showing signs of infection. Quarantine will likely only be needed during infectious disease disasters. Additional information on quarantine is provided in **120. Infectious Disease Disasters: Bioterrorism, Emerging Infections, and Pandemics**.

Occupational Health Issues

Most employee health decisions fall under the occupational health department. However, some employee health issues that arise during mass casualty incidents have infectious disease implications and must therefore have IP involvement. Examples include staff assignment to potentially contagious patients; cohorting of patients or staff; allocation of limited doses of anti-infective therapy, prophylaxis, or vaccination; and distribution of limited protective equipment. Protocols must be developed that outline procedures for following up on staff work exposures; delineating prioritization plans for limited doses of anti-infective therapy, prophylaxis, or vaccination; and allocating PPE when supplies become insufficient

or depleted. Staff at high risk from infection (i.e., pregnant or immunocompromised individuals) and high-risk procedures (such as aerosolizing procedures during an outbreak of a droplet or airborne spread disease) should be identified as part of emergency management planning. Protocols should be developed that address how to decrease risk to these individuals, such as reassignment or furlough.[18]

Food and Water Safety

The most serious health hazard after most types of mass casualty incidents is the deterioration in environmental conditions, particularly in water supply and disposal of human wastes.[8,9]Water is essential for numerous healthcare facility functions. Drinking water must be available immediately. A minimum of 2 liters per person per day must be provided for both patients and workers. Water will also be needed for hand washing, bathing, washing dishes, washing linen, sterilizing, cooking, dialysis, processing of scopes, hydrotherapy, flushing toilets, and other purposes. Waterborne diarrheal illness is a major concern after natural disasters in camps among displaced individuals and can have a high mortality rate.[38]It is vital that water safety practices be implemented after natural disasters.

During emergency management planning, estimate the amount of water that would be needed to maintain patients, HCP, and necessary healthcare facility functions for a minimum of 3 to 5 days. Backup water supplies should provide 25 gallons/day per patient. Federal agencies may be able to provide portable water purification systems and power generators. Determine how much water should be stored on-site, how much could be stored off-site, and how much could be obtained from outside resources at the time of the mass casualty event. Methods for gaining access to water resources should be described in the emergency management plan. Contracts or memoranda of agreement should be developed as part of the emergency management planning process.

If water quality is uncertain, it may be purified by (1) boiling for 1 minute, or (2) adding 1/8 teaspoon of bleach per gallon. Mix thoroughly and allow to stand for 30 minutes before using.[39]

During the response phase, tap water should be tested immediately. The role of the individual authorized to assess the water quality should be specified in the emergency management plan. Whenever water quality is questionable, clearance should be obtained from public health officials before resuming use. If its appearance or pressure is different from usual, use should be restricted. Communication regarding water safety will be essential to protect staff, visitors, and patients. New technologies now exist for treating existing water on-site rather than continuously transporting in bottled water, a practice that is more sustainable and affordable.[40]

Sources should be prominently labeled or hooded to restrict use. The plan should specify how this would be done. Assess inside or outside water resources, and plan for distribution. Water is an important resource that must remain available. On-hand quantities must be tracked as part of ongoing resource assessments taking place during the disaster response.

Food must be provided for all individuals who will remain on the premises, including quarantined individuals. Balanced meals are necessary to both physical and psychological health. During emergency management planning, food requirements needed for a mass casualty incident should be determined. Patients and staff must be included, and other groups (e.g., visitors who are present, clinic patients, and family members of the staff) should be considered. This decision should be included in the emergency management plan, and an estimate should be provided of the number of people needing to be fed.

As part of emergency management planning, the power supply to the dietary department should be assessed to ensure that food safety would be possible following a mass casualty event. At least one refrigerator and freezer should be on emergency power. Assess the adequacy of temporary lighting, if emergency power should be unavailable for an interval. Review the emergency management plan for the dietary department. It should specify the order in which food will be used to ensure food safety: (1) refrigerated food on hand, (2) food from unpowered freezers, and, lastly, (3) disaster reserve supplies. The tendency is generally to rush into reserve supplies too fast, while food in an unpowered refrigerator becomes unusable. Plan to provide food for staff (and others as you choose) as soon as the response phase begins. Available food provides both a psychological reassurance that the situation is under control and a physiologic calming effect from the stimulation of the parasympathetic nervous system, with resulting inhibition of the sympathetic nervous system.

During the mass casualty event response, food service practices must be monitored for basic sanitation. Monitor holding temperatures and the length of time food is held in the danger zone (45°F to 140°F).[21]Food that requires refrigeration that has been kept at room temperature for 2 or more hours or any food that has been kept for an hour or more in a room above 90°F should be discarded.[21]Contaminated food, most often associated with poor water safety, can result in high mortality (up to 40 percent) if diarrheal illness occurs.[38]

Sewage and Sanitation

Trash pickup may not occur as scheduled following a mass casualty incident. The emergency management plan should identify areas for sanitary storage of solid waste as well as regulated medical waste until routine sanitation practices can be resumed. In addition, toilet facilities must be available with minimal delay during a disaster. The emergency management plan should specify both short-term and long-term plans for meeting this need.

The most critical information needed will be the function of the sewer system. Earthquakes may break sewer lines; floods or hurricanes may overwhelm them. A fire or tornado would probably leave them intact. If sewer disruption is a possibility, define in the emergency management plan who will assess their function and how the results will be communicated. It is an urgent priority that toilets not be flushed if the sewers are broken, as this will result in a flood of heavily contaminated water at some unspecified location. Negotiate service contracts with a reliable chemical toilet company. Clarify whether the company can assist with disposal of wastes collected before their arrival. Decide how many units will be needed and where they will be placed, remembering that they must be accessible to the servicing trucks (a location near an outside drain is ideal).

Plan for temporary toilet facilities for the hours before the chemical toilets can be delivered. There is no aesthetic solution to this problem, and all solutions have advantages and disadvantages. A few solutions include (1) three plastic bags in a bucket, (2) one small bag for one use only, and (3) commercial disposable urinals. The military solution of a trench is not suitable for urban environments.

Advantages to the three plastic bags in a bucket include using readily available materials and a quick setup. Tie each bag separately, and store used bags in a leak-proof container, such as a garbage can, until the chemical toilet company can collect them. Disadvantages are that they must be monitored to prevent overfilling and that this method is not pleasant. Addition of a gel powder could be considered.

Single-use small bags also use materials on hand and are a cleaner option. Disadvantages include requiring a large supply of bags, the danger of leakage, and storage of used bags.

Commercial disposable urinals can be used either individually or to fit commodes. These are relatively aesthetic, but involve added expense. One disadvantage is that they must be preplanned and on-site before the disaster strikes.

If sewer disruption is likely, the emergency management plan should address whether the healthcare organization should remain in a building without this function. This is a factor to consider in making a decision on building evacuation. If sewers are intact, better alternatives are available, even if the water supply is interrupted.

Pouring a bucket of water down a toilet may allow temporary flushing when water service is not available, and the water used need not be clean. A crew could make rounds with a large can of water on a cart. This method works well, but is labor intensive. One flush may be available in the system. The disadvantage with this is that it is often wasted early, and then is no longer available. Use toilets without flushing until better arrangements can be made. This is not aesthetic, but it is safe if the sewers are intact.

Bedpans may be emptied into whatever container is in use for ambulatory people. Consider discarding heavily soiled bedpans, if supplies permit. An alternative is to place the pan inside a large plastic bag before use, molding the bag inside the pan to form a liner that can be discarded after use.

Anti-Infective Therapy and Vaccination

Some mass casualty events, especially biological events, may require the use of anti-infective therapy or mass vaccination interventions. Vaccine-preventable diseases that are endemic to the area hit by disaster pose the biggest risk postdisaster. For example, areas with endemic measles have experienced measles outbreaks in camps and shelters following natural disasters.[38] It is important to consider mass immunization during a measles outbreak that occurs in a disaster-affected community (such as in a community evacuation shelter) or during an infectious disease disaster.

Programs designed to distribute mass treatment, prophylaxis, or vaccination in a short period of time require unique interventions. Sites used for mass distribution of anti-infective therapy or vaccination are known as PODs. Their success will be dependent on advance planning, coordination, and communication among many groups and agencies. PODs are most effective when located off hospital property to keep noncritically ill individuals away from hospitals and treatment centers. An exception to this is facility-based occupational health programs that may distribute treatment, prophylaxis, or vaccination to employees. Information on how to implement infection prevention practices in PODs have been published.[22] Additional information on anti-infective therapy is provided in **120. Infectious Disease Disasters: Bioterrorism, Emerging Infections, and Pandemics**.

Decontamination

Decontamination is the reduction or removal of chemical or biological hazardous agents.[23] There are two means of decontamination: physical and chemical. Physical decontamination includes removing the hazardous agent through physical means, such as washing, scrubbing, or rinsing. Chemical decontamination is the use of chemical agents to remove hazardous agents.

Decontamination may or may not be necessary after a mass casualty incident, depending on the following factors: (1) type of mass casualty event, (2) how soon the event is identified, and (3) source of concern (environment or patient). For most mass casualty incidents, patient decontamination will not be necessary. One exception to this is a chemical terrorism attack, following which rapid, appropriate patient decontamination will be necessary to decrease morbidity and mortality. Patient decontamination

may also be necessary after a bioterrorism attack (see **120. Infectious Disease Disasters: Bioterrorism, Emerging Infections, and Pandemics**). For many mass casualty incidents, patient decontamination will occur either at the site of the event or another off-site location designated for decontamination procedures.[23] Despite this, hospitals and healthcare facilities should be prepared to perform patient decontamination as part of having an all-hazards emergency management plan.

Patient Decontamination

Patient decontamination begins with the removal of contaminated clothing. If removal is indicated, patient clothing should be handled only by personnel wearing appropriate PPE and placed in an impervious bag to prevent further environmental contamination.

Patient decontamination recommendations for biological terrorism are different from those for certain chemicals, such as blister agents, which may respond better to dry powder decontamination compounds.[41] However, these powder agents are not widely available in the civilian population. For that reason, some hospitals or communities may choose to use traditional soap and water decontamination, regardless of the chemical agent to which the patient was exposed. After removal of contaminated clothing, patients should be instructed (or assisted, if necessary) to immediately shower with soap and water, to include the shampooing of hair. Potentially harmful practices, such as bathing patients with bleach solutions, are unnecessary and should be avoided. Clean water, saline solution, or commercial ophthalmic solutions are recommended for rinsing eyes. Another option is to use baby shampoo because it does not sting the eyes during rinsing. Special consideration must be made for children and elderly persons during patient decontamination. Children are at higher risk from hypothermia than adults, especially following decontamination. Warming blankets, heat lamps, warmers, and other such equipment must be on hand to accommodate children during patient decontamination procedures.[41]

Whenever possible, warm water and decontamination facilities that can accommodate families should be made available.

Environmental Decontamination

Environmental decontamination is the removal of chemical or biological hazards from inanimate objects. Although environmental decontamination will not be necessary for most types of mass casualty incidents, it may be required in some circumstances.[41] Indoor environmental sources may require decontamination strategies following any type of mass casualty incident that results in flooding, overcrowded living conditions, or lack of clean water. An example of this is the cleaning/disinfection of alternate care sites and community evacuation shelters that is necessary following a mass casualty event.[21,23] An environmental inspection and cleaning/disinfection will be needed before reopening a room, floor, or building after it has been closed for a length of time.

Environmental decontamination will also be necessary after any mass casualty incident that involves a hazardous or infectious agent that is spread by hand-to-hand contact or contact with fomites. Some examples include a chemical terrorism event or bioterrorism attack using smallpox, anthrax, or a viral hemorrhagic fever agent. Environmental decontamination in these circumstances includes the disinfection of all horizontal surfaces using a healthcare facility-approved EPA-registered product (see **120. Infectious Disease Disasters: Bioterrorism, Emerging Infections, and Pandemics**). The use of more stringent PPE may be needed for decontamination of surfaces contaminated by chemicals. The Department of Defense website (**http://www.defenselink.mil/**) provides more information on decontamination strategies following a chemical terrorism attack.

Postmortem Care and Morgue Surge Capacity

In any disaster, some level of mortality is expected. Provisions must be made in advance for storage and/or transport of corpses. Most morgues can house no more than a dozen bodies. How will the facility or community morgue handle a greater number of victims (i.e., have morgue surge capacity)? Consider planning an off-site location to be used as a temporary morgue, and arrange for the services of a local mortician to handle transport of fatalities. Be sure that adequate supplies of body bags can be obtained. For most disasters, individual burial is preferred over cremation or mass burial.[8]The risk of disease transmission from corpses to the living is very low after most disasters; exceptions would include victims who had cholera, smallpox, or viral hemorrhagic fever.[8]

Pet Management

Disasters that require displacement of individuals, such as floods, hurricanes, or earthquakes, may result in patients, visitors, or staff bringing pets to hospitals or healthcare facilities. Management of service animals for disabled individuals or those that are used for healthcare-related procedures are covered in **122. Animals Visiting in Healthcare Facilities**. Pets differ from service animals; hospitals cannot accept pets because of health and safety regulations. Because pets may be brought to the hospital during a mass casualty incident, healthcare facilities should coordinate with community emergency managers to arrange for pet placement in the event of a mass casualty event. During a disaster, hospitals should communicate with staff regarding where they can take their pets for temporary placement/housing in the community if displacement is necessary.

Pest Management

Natural disasters, especially hurricanes and floods, are likely to result in an increase in insects and other pests in or around the affected community due to rain and high water levels. Healthcare facilities may become infested with insects and/or vermin seeking warmth, moisture, and food. Some insects and animals may be bothersome only, but others can spread disease. Examples include the link between mice and hantavirus, or mosquitos and West Nile virus. Rodents, such as rats and mice, can spread disease by contaminating food and the environment or by biting/scratching humans. Pests can also invade medical supplies.

The following environmental controls should be implemented to minimize pests after disasters: (1) store garbage and medical waste in closed containers located away from the facility, (2) do not have open boxes or pipes within the facility as these can become nests or breeding grounds for pests, and (3) obtain pest control services as needed, including spraying for mosquitos or setting traps for mice. In addition, the facility's physical structure should be evaluated for any possible entrances for pests, and if found, should be eliminated. Examples include windows with torn or missing screens, unclosed doors that lead to the outside of the building, or sources of standing water.

Natural disasters may prevent routine garbage collection from occurring; delayed waste removal increases the risk for rodent infestation. To minimize this, food and water safety protocols should be implemented, including storing food and water in rodentproof lidded containers consisting of glass, thick plastic, or metal.

Healthcare agencies should develop protocols for safely capturing, killing, or eliminating rodents that get into the facility. Guidelines for developing these procedures are available from the Centers for Disease Control and Prevention (CDC).[42]

Vulnerable and Special Needs Populations

Although disasters can strike any community and affect people of all ages and races, regardless of health status, certain groups of individuals are more at risk from morbidity and mortality during mass casualty incidents. These individuals with special needs are known as special needs or vulnerable populations. Children, elderly persons, those who are immunocompromised, and pregnant women are examples of such groups.[43]Meeting the needs of vulnerable groups must be addressed as part of disaster planning and included in the emergency management plan at the facility and community level.

Special needs individuals are those who may need additional assistance before, during, and after a mass casualty incident in terms of maintaining their independence, communication, transportation, supervision, and access to medical care. This includes individuals who are disabled, live in institutionalized settings, or who lack transportation. Special needs individuals also include those who speak limited or no English and may have difficulty communicating with response agencies and those who are very young (pediatrics) or elderly who may be at an increased risk from morbidity or mortality from the mass casualty event.[43]

Disabled Individuals

The term "disabled" describes a broad range of afflictions that affect individuals, including conditions that impair hearing, sight, speech, and mobility. The type of disability affects how the individual can respond to a mass casualty incident. For instance, individuals with limited mobility may need extra assistance during disasters that require evacuation and require special accommodations for transportation. In addition, disabled individuals may need specialized medical equipment/supplies, such as service dogs/animals, hearing aids, translators/interpreters, walkers, wheelchairs, etc.[44]Historically, emergency management plans have lacked sufficient accommodations for disabled individuals, which has placed these individuals at risk during mass casualty events.[44]It is important to address disabled individuals in all facility and community emergency management plans.

Pediatrics

Children are at increased risk from disasters because of physiological, psychological, sociological, and developmental reasons. Young children, especially those under the age of 5, have a significantly higher mortality rate during mass casualty incidents than adults.[45]Children have a higher respiratory rate than adults and disproportionate body surface area-to-weight ratio, which puts them at risk from inhaling aerosolized biological or chemical contaminates or absorbing environmental toxins through the skin.[41]

Children are also at higher risk than adults from head and chest injuries, musculoskeletal, and spinal injuries during mass casualty incidents due to a variety of physiological reasons.[46]Hypothermic and hyperthermic injuries and thermal regulatory problems are more common in children than adults after mass casualty events because of children's body surface to body mass ratio. Volume depletion also occurs more rapidly in children than adults, making hydration an important consideration when caring for children after a mass casualty incident. More information can be found in **42. Pediatrics**.

Young children have limited mobility, cognitive, and communication skills/abilities, which put them at risk during mass casualty events. Children may not be able to get away from the disaster or let others know that they need assistance. Newborns and children with immunodeficiencies are at an increased risk from infection, especially during an infectious disease disaster.

Healthcare facilities should consider that they may receive pediatric patients during mass casualty events, even if the facility is not a traditional pediatric hospital. Past mass casualty incidents indicate

that most children receive medical care in general hospitals rather than pediatric facilities during mass casualty events.[45]Hospitals need to be prepared to address pediatric concerns during disasters,

including the need for special medical equipment/supplies that are specific to children. Examples of such equipment include different doses of medications (sometimes based on the child's weight), smaller endotracheal tubes, needles, intravenous kits, linens, warming supplies for patient decontamination, etc. Community resource sharing would be appropriate and should be coordinated through the community emergency management reporting structure. Healthcare facilities also need to address pediatric concerns during disaster drills, something that has historically been neglected.[45]

Geriatrics

Elderly individuals are at an increased risk of morbidity and mortality following mass casualty incidents due to normal physiological changes, such as decreased mobility, impaired sight and hearing, and declining response to immunizations and medications. Most elderly individuals have a pulse/temperature dissociation that masks the signs of infection, making diagnosis much more difficult than in adults or children.[47]In addition, cognitive impairment and/or altered mental status changes common in elderly

persons put this group at risk during disaster response. Frail elderly persons and those who live in institutionalized settings such as long-term care or nursing homes, assisted living, mobile home parks, and subsidized housing are especially vulnerable to mass casualty events due to limited mobility and multiple underlying medical illnesses.[47]Individuals with comorbidities, such as diabetes, cardiovascular

disease, and hematological alterations, are at an increased risk because they may have limited access to medical care or pharmaceuticals during disaster response or may have adverse reactions to medications due to drug interactions. More information on elderly persons can be found in **40. Geriatrics**.

Healthcare facilities, including hospitals and long-term care centers, must include accommodations for elderly persons in their emergency management plan. Extra time will be needed to evacuate areas that house frail elderly persons, and staff must be trained on how to perform these procedures. Communication between facilities is essential to providing seamless continuity of care if elderly persons are to be transferred during a mass casualty incident. Coordination will be required between the hospital and other healthcare agencies, such as home care, if elderly persons are discharged during disaster response to provide hospital surge capacity for victims from the event.

Immunocompromised Persons

Immunosuppression results in an increased risk for disease, and mass casualty events can heighten this risk due to the inherent stress involved in the event. Immunocompromised individuals can be expected to have increased complications and mortality rates following a mass casualty incident compared to healthy adults; this is especially true during infectious disease disasters such as bioterrorism, an outbreak of emerging infection, or a pandemic.[48]Very little is known about disease presentation in

immunocompromised hosts, but it is believed that these individuals will likely have unusual disease presentation, which will complicate and possibly delay diagnosis.[48]Immunocompromised individuals with

comorbidities are at an increased risk because they may have limited access to medical care or pharmaceuticals during disaster response or may have adverse reactions to medications due to drug interactions. More information can be found in **23. The Immunocompromised Host**.

Pregnancy

Normal physiological changes during pregnancy, such as a somewhat compromised immune system, decreased ventilatory capacity, and increased respiratory tract bacterial growth, put women at an increased risk for infectious diseases. Research indicates that pregnant women are at increased risk for influenza, malaria, hepatitis, measles, and smallpox compared to nonpregnant individuals.[49]Stress of any kind, especially during mass casualty incidents, enhances this risk and has been linked to preterm labor and low birth weight.[50]Pregnant women are most at risk during an infectious disease disaster. Mortality rates were higher for pregnant women than for nonpregnant individuals during the severe acute respiratory syndrome (SARS) outbreak of 2003, the 1918 influenza pandemic, and during past smallpox outbreaks.[51]Risks exist for the fetus as well. Infectious diseases that develop in pregnant women during mass casualty events, such as past outbreaks of SARS or smallpox, can lead to spontaneous abortion or preterm birth.[51]In addition, many medications or vaccinations that might be needed during a mass casualty incident to treat or prevent disease in pregnant women could harm the fetus.[50]Examples include smallpox vaccination and live attenuated vaccines.[50]More information on pregnancy can be found in **104. Pregnant Healthcare Personnel**.

Procedures for continuing to provide prenatal care, labor and delivery services, and newborn care during mass casualty incidents must be included as part of emergency management.[51,52]Healthcare facilities may choose to limit or eliminate labor and delivery services provided by their facility during a mass casualty event as a means of increasing surge capacity for disaster victims.[52]If this is done, hospitals must develop algorithms for determining who would receive limited beds and designate which groups of pregnant women would be triaged to an alternate care site set up in the community or possibly referred for home birth.[50]During an infectious disease disaster, hospitals may elect to only provide labor and delivery services off-site as a way of physically separating pregnant women from potentially contagious patients. This procedure was effective at decreasing disease transmission during the 2003 SARS outbreak in Canada.[52]

Transportation

Transportation problems may affect a healthcare facility's ability to respond effectively to a mass casualty incident. Transportation routes need to be predetermined to allow patients, visitors, staff, and supplies to get where they need to be in a safe, rapid manner. A mass casualty event may bring large influxes of patients and the worried well, which can result in chaos if transportation routes are not predetermined. In addition, it is critical to predetermine alternative transportation routes for supplies. Temporary triage centers, ambulance entrances, and loading areas may be needed to accommodate the increased traffic. Transportation during a mass casualty incident can have infectious disease implications, so it is important to make sure that patient flow is constructed in a manner that decreases disease spread. An example is to set up separate triage areas for assessing potentially contagious people during an infectious disease disaster.

Communication and Reporting Systems

Communication refers to both the physical means of communicating information (radios, telephones, etc.) and the messages that are being communicated (risk communication). Healthcare facilities must maintain the ability to communicate between departments (internal communication) and with outside agencies (external communication) during a mass casualty incident. A backup communication system should be available in case the standard system becomes inoperable or overwhelmed. In addition, auxiliary power and secondary sites need to be established prior to an incident, and individuals need to

be trained to use the communication system. Consider keeping two-way radios where they will be needed, such as in security and the emergency department. Also consider the use of "disaster first response script cards" to describe first critical steps, such as location of all staff and patients, prevention of fire, and turning off of oxygen and nonessential electrical equipment to avoid the need to locate cumbersome manuals during the stress of first response. Posters are also an effective means to communicate disaster triage and patient management strategies and algorithms.

In the event of a mass casualty event, a facility's emergency management plan will be implemented in tandem with other local, state, and federal emergency management plans. A coordinated effort is essential, regardless of the number of casualties or agencies involved. Such coordination depends on effective internal and external communication. Governmental emergency management plans are based on the National Response Framework (NRF), National Incident Management System (NIMS), and the Incident Command System (ICS), a series of principles designed to be implemented during an emergency.[53]ICS is an appropriate and effective framework for an emergency management response system, and it is both a communication and a reporting system.

ICS builds a framework for working and reporting during the response effort that is based on the need for workers to be flexible and to realize it will not be "business as usual." This means that employees may not be working in their typical roles or departments nor will they be reporting to their usual supervisors. This can be unsettling for many people. Being familiar with ICS helps people know what to expect and what their responsibilities and accountability will be during the mass casualty event.

Under ICS, individuals are assigned specific roles and a distinct chain of command comes into effect. Specific job responsibilities and parameters are defined in job action sheets and the organizational structure is outlined. It is best to practice ICS as part of emergency management planning exercises to ensure that participants understand its principles.

An excellent model for ICS in healthcare agencies is the Hospital Incident Command System (HICS).[53]In essence, HICS is an ICS modified to meet the specific needs of hospitals. Detailed information on HICS can be obtained online.[53]

The use of HICS as an emergency management system ensures that the hospital or healthcare facility will be able to quickly and effectively communicate with outside agencies, including law enforcement, emergency medical services, and fire and governmental agencies. The faster an effective communications network and emergency management plan is in place, the sooner the hospital can recover from the emergency incident and return to day-to-day functioning. This is advantageous to both the healthcare facility and the community it serves. HICS needs to be incorporated into the facility's emergency management plan as part of the organizational hierarchy and communication network specific to the management of the incident. Use of HICS also helps hospitals conform with NIMS requirements.

In HICS, new organizational charts are developed for use during the disaster response effort (Figure 119-3). Each position has a specific mission, and a job action sheet describes the responsibilities assigned to each. Two advantages of having written job action sheets are that they prevent clashes between individuals based on normal lines of authority in the workplace and they prevent duplication or confusion over job responsibilities.

Figure 119-3.

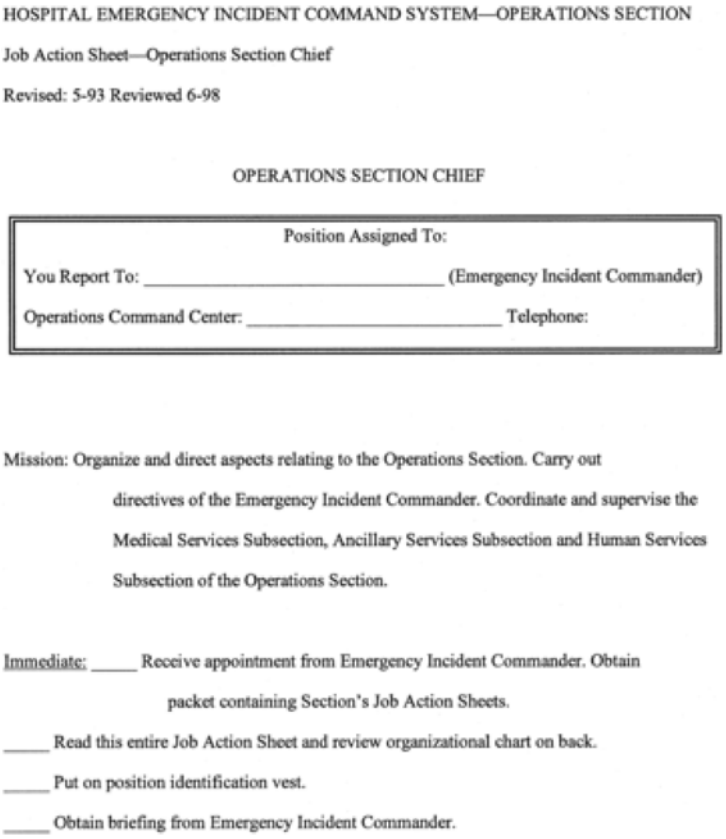
Hospital emergency incident command system organization chart.

View Image

The U.S. Department of Health Services recommends instituting HICS in its original form.[53] Once the system is in place and the facility exercises its emergency management plan, however, minor modifications may be made. Some aspects of HICS should remain unchanged, in order to maintain continuity and avoid confusion within the facility and between the facility and outside agencies. For example, the mission statement or position title on the job action sheets should not be changed, but the checklists on the job action sheets can be modified. See for an example of a section of the HICS Operations Section Chief Job Action Sheet that covers the first 2 hours of a mass casualty incident. Always refer to the HICS training manual to determine which facets may be altered without compromising the integrity and effectiveness of the emergency management plan.

Another consideration when assessing and planning communication systems is to prearrange congregation areas for media and transportation routes. Following a mass casualty event, media coverage will be 24 hours a day, 7 days a week. Media groups will flock to the healthcare facility to obtain information and updates. Advance planning can help reduce traffic congestion and disruptions to patient and visitor flow.

During disaster response, communication is one of the most critical components of the response. Experience with emergency management plan exercises and real disasters has shown that one of the largest gaps has been in establishing and maintaining effective communication.[54] Facilities must be able to communicate both internally between departments and externally with outside agencies. In addition, communication with the general public in the community will be critical. During a crisis, accurate consistent messages must be provided to the public, as well as information regarding who is at risk and how those groups can quickly obtain treatment. IPs are unlikely to be the primary means of communication during disaster response but will play a role in overall coordination of the response and in development of media messages for the general public. Risk communication strategies should be utilized when communicating with the public after disaster strikes. See the section on risk communication in this chapter.



Communication needs will include education that takes place within the organization, in outside agencies, and with the general public. In addition, communication will involve the sharing of patient-related information with the public health departments, both local and state. Due to new confidentiality regulations, such as the Health Insurance Portability and Accountability Act (HIPPA), patient information cannot be shared between hospitals or healthcare institutions, but certain information can and should be provided to the health department performing the epidemiology investigation or while conducting syndromic surveillance.[55]

Another important component of communication during the response phase is assisting in criminal investigations. Some mass casualty incidents, such as biological or chemical terrorism, are crimes and will be extensively investigated by the FBI. As part of the investigation, the FBI will be gathering evidence, requiring participation from both healthcare and public health agencies. These procedures are new to most healthcare professionals; forming partnerships with federal agencies in advance will make

working together easier in the time of crisis. IPs do not need to know how to gather evidence correctly, but they do need to know how to communicate a potential event to the correct agencies so that the investigation can be initiated.

Information is scarce and valuable in the community disrupted by mass casualty event and can be used to help convince the general public to act in the best interests of the community as a whole. If there is a need to control where the public collects (e.g., away from the emergency room entrance), place a source of reliable information (a TV set or frequently updated bulletin board) where you want the crowd. People will need to discuss their experiences as they work to comprehend them, and this can take place around the information source. This has good potential for rumor control. Information can also be shared as part of staff debriefing, which should decrease employees' stress and anxiety.[56]

During the recovery period, communication will be less stressful and intense than during the disaster response. Recovery communication will involve (1) dissemination of the epidemiological investigation findings, (2) sharing lessons learned between departments and with outside agencies, (3) evaluation of communications that took place during the disaster response, and (4) gap analysis for future mass casualty incidents. Interventions may need to be planned to fill gaps identified during the response before a future event occurs. For instance, a lack of radios may be identified as a barrier to effective disaster communication; the purchase of additional radios would then be a priority.

HOSPITAL EMERGENCY INCIDENT COMMAND SYSTEM—OPERATIONS SECTION

Job Action Sheet—Operations Section Chief

Revised: 5-93 Reviewed 6-98

OPERATIONS SECTION CHIEF

Position Assigned To:

You Report To: _____ (Emergency Incident Commander)

Operations Command Center: _____ Telephone:

Mission: Organize and direct aspects relating to the Operations Section. Carry out directives of the Emergency Incident Commander. Coordinate and supervise the Medical Services Subsection, Ancillary Services Subsection and Human Services Subsection of the Operations Section.

Immediate: _____ Receive appointment from Emergency Incident Commander. Obtain packet containing Section's Job Action Sheets.

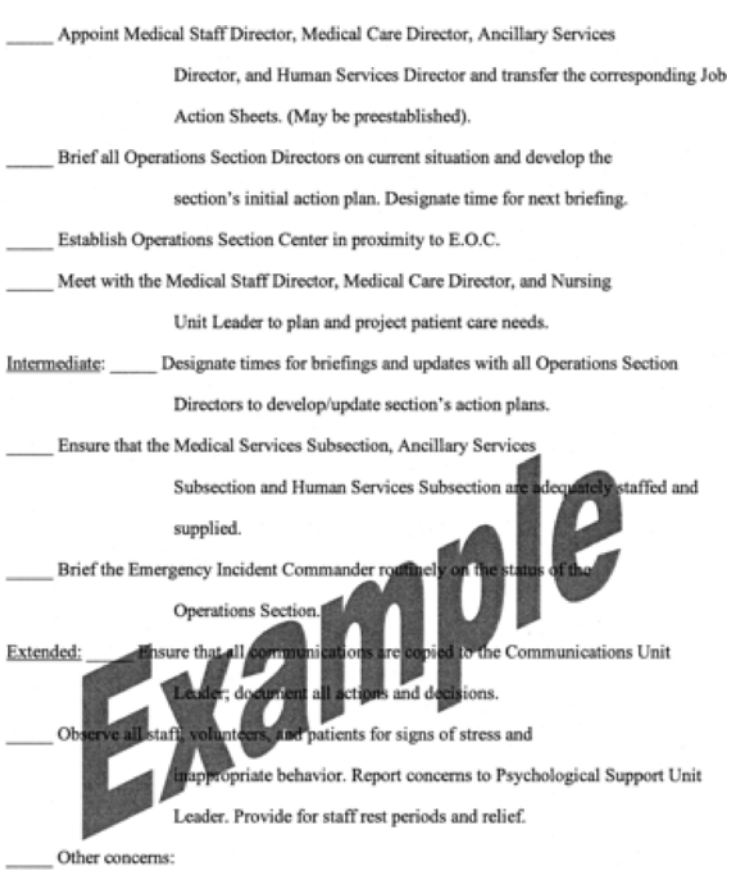
_____ Read this entire Job Action Sheet and review organizational chart on back.

_____ Put on position identification vest.

_____ Obtain briefing from Emergency Incident Commander.

Figure 119-4. Example of a HICS job action sheet (operations section chief) View Image

Figure 119-5.



Example of a HICS job action sheet (operations section chief).

Risk Communication and Pre-event Messaging

Mass casualty events cause both physical and psychological stress. Communication of needed information before, during, and after a mass casualty incident is essential for preparing individuals and groups for disasters before an event occurs, as well as controlling rumors, maintaining calm, and disseminating response information to those affected during and after an event.

Risk communication is an evidence-based approach to communicating information to professionals and lay people during times of disaster or other high-stress events. It involves communication designed to motivate individuals into action or preventing them from taking an inappropriate action, depending on the situation. For example, media messages from a hospital could explain the following: (1) why, how, and where community residents should obtain vaccination following a flood; (2) the potential consequences of not obtaining vaccination during a bioterrorism attack or pandemic; (3) which groups require and do not require vaccination; and (4) which interventions cause harm or are not helpful. It is also important to note that clinical information can change rapidly during a

mass casualty incident and changes in practice must be communicated quickly to staff, such as during the 2009 H1N1 pandemic.[27]The need to communicate changes in practice will be most important during an outbreak of an emerging infectious disease in which little is known about the disease or during an unusual scenario such as a bioterrorism attack.[27]Past research indicates that fear and mistrust are common among HCP and first responders during events necessitating new or changed practice standards; these changes must be effectively communicated to staff to prevent disease transmission and encourage employees to continue working during the mass casualty event. Failing to communicate effectively during a mass casualty incident can have long-lasting implications and can negatively affect citizens' trust in healthcare and public health during future events.[57]The 2001 anthrax incident taught healthcare and public health important lessons about the need to communicate more effectively with the general public. If confusing and contradictory information is communicated during a mass casualty event, people may refuse to follow recommended treatment regimens that can lead to secondary disease transmission and higher morbidity and mortality.[57]Research with the general public indicates that citizens are likely to comply with recommendations if the information source is deemed credible.[58]

Whenever possible, it is best to develop messages in advance; doing so allows a rapid, organized, objective response. This is called pre-event messaging; it means that messages are determined prior to an event. These messages serve a number of functions, including: (1) imparting information, (2) updating citizens on the progress of the event, (3) instructing the public how to obtain medical care and which measures to take to protect themselves, (4) dispelling rumors, and (5) instilling or maintaining calm. The CDC and the Association of Schools of Public Health (ASPH) have collaborated on a multidisciplinary and multistate research project to determine the content and effectiveness of pre-event messages related to biological, chemical, and radiological/nuclear terrorism. This research not only identified citizens' primary concerns about mass casualty incidents that must be addressed in pre-event messages but also identified terms that needed to be revised and/or clarified to have the strongest impact.[58]Pre-event messages were created and tested for a number of different scenarios, including infectious disease disasters, and in a variety of formats for dissemination, including radio live reads, narrated television clips, and fact sheets.[58]Findings from this research indicate that pre-event radio and television messages are less effective than written information because the general public interpret them as not credible.[58]Therefore, it is recommended that healthcare and public health agencies develop written educational materials for use during a mass casualty event. They should also be included in the agency's emergency management plan. If televised media messages are to be used during an event, it is best to use public health officials as spokespeople, because research indicates that televised media

messages pertaining to emerging infectious diseases that used a public health official as the spokesperson were 15.2 times more likely to contain accurate, high-quality information.[59]

Documentation

During a mass casualty event, sensory overload sets in within minutes, making it very difficult to take in and process information. Every individual responsible for emergency management should maintain a detailed log, beginning as soon as possible after the mass casualty incident and noting first the time of the disaster and what is immediately known. This log will be a priceless resource for sequencing events, tracking accountability for decisions, and writing reports. Some experienced professions consider keeping of the disaster log the single most useful piece of advice. Documentation is also vital for the facility to receive reimbursement for the event from federal funding.

Education and Training

Staff education and training is part of healthcare facility emergency management planning to ensure that the staff understands the basics about emergency management. Topics include (1) types and consequences of mass casualty events, (2) the facility's emergency management plan, (3) staff's role in the emergency management plan, (4) how to recognize and respond to a mass casualty incident, (5) appropriate reporting and communication systems in place during disaster response, and (6) how and when to practice disaster response strategies. A full list of educational topics that IPs need to cover for staff, patients, and visitors has been outlined in the literature.[4]Education should be provided to all staff, both medical and support services employees, and should be specific to each worker group. Infection prevention competencies for hospital-based HCP have been identified, including competencies related to emergency management, and should be used as the basis for education and training.[60]

During a mass casualty event, it may be necessary to create and disseminate educational materials. Ideally, such disaster-related educational materials should be created during emergency management planning. If not, they must be created during or after the mass casualty incident to aid in response efforts.

The materials should be event specific. For example, in the event of a mass casualty event involving a contagious agent, such as a smallpox bioterrorism attack, they will need to address control and isolation measures, treatment requirements, and prophylaxis or vaccination recommendations. Educational materials should also address how staff, patients, and visitors can protect themselves and their community during the response. Some of the information provided will concern (1) water safety, (2) sanitation control, (3) proper food preparation (temperature control, etc.), (4) agent-specific information (route of transmission, treatment, etc.), (5) isolation precautions, (6) prophylaxis, (7) vaccination, and (8) control measures.

Some staff members may not be able to get into the hospital, and inexperienced staff members who have not received infection prevention orientation may be at the bedside. Determine what information is necessary for patient and staff safety, such as Standard Precautions and the use of PPE. This information should be communicated as simply as possible, using as little time commitment as possible because the IPs will most likely be tied up with other disaster-related duties. These quick educational messages may be accomplished through posters, pocket cards, or other written methods.

Public health agencies are a valuable resource for educational materials, though their staffs will be strained by events as much as the rest of the community. They may be able to provide educational

resources for the following: (1) supplying safe water, (2) coordinating requests for help from outside, and (3) managing outbreaks of communicable diseases, especially childhood rash illnesses.

Education and training during the recovery period should focus on (1) dissemination of information on the effectiveness of the disaster response, (2) areas for improvement related to disaster response, (3) changes/updates to the emergency management plan, (4) ongoing infection prevention strategies, and (5) results from data gathered during the epidemiological investigation when applicable.

Evaluating Preparedness

Evaluating preparedness is accomplished by evaluating the written emergency management plan and practicing the plan either through drills and exercises or from response to actual mass casualty incidents. Planning checklists have been created to aid in evaluation of the infection prevention components of written emergency management plans.[18,19,22] Some regulatory agencies, including TJC, require regular execution of hospital emergency management plans, either through response to an actual disaster or by holding an exercise at least twice a year.

Emergency Management Plan Evaluation Following a Disaster

Emergency management plans should be evaluated following response to any mass casualty event. This should be done after the crisis has dissipated from the event. How effective was the emergency management plan? Was staff familiar enough with the plan to implement it effectively? Were there facets of the plan that did not work as effectively as possible? Are there areas that can be improved before the next mass casualty incident strikes?

It is critical for the facility to hold a debriefing session in which all of the responding departments and agencies discuss what was learned from the situation. Furthermore, this information should be used to generate an after-action report. This will be greatly facilitated by the availability of any disaster logs that individuals or departments maintained during the mass casualty event. Once the lessons learned from the event have been discussed and documented, the emergency management plan must be updated. If a facility discovers during response to a mass casualty incident that more decontamination gear is needed and more staff should be educated in its use, this information should be incorporated into the after-action report. Thus, a facility might institute a mandatory quarterly drill for decontamination staff to practice donning protective gear and simulating the decontamination process.

Disaster Drills and Exercises

Because most mass casualty events cannot be anticipated and TJC requires twice yearly emergency management plan execution, most healthcare facilities and communities will need to conduct drills and exercises to evaluate their emergency management plan. It is important to note that TJC requires full execution of the emergency management plan during the two exercises and that one exercise must be a community-wide drill; tabletop exercises that only involve discussion of emergency management protocols do not meet this standard.[18]

Disaster exercises/drills provide many benefits, including an opportunity to (1) identify and correct gaps in planning, (2) clarify participants' roles and responsibilities, (3) enhance coordination with internal and external agencies, (4) demonstrate how to implement the plan, and (5) introduce participants to the new reporting and communication structure. Exercise programs can make the difference between a poor and an effective response, which translates into lives and resources saved.

To conduct a healthcare facility disaster drill/exercise, the following steps are involved: (1) develop objectives for an exercise (i.e., the components of the emergency management plan that are to be

evaluated); (2) conduct an exercise, during which the emergency management plan is practiced; (3) discuss the findings of the exercise in relation to the identified objectives; (4) identify gaps in preparedness as illustrated by the exercise; (5) determine solutions to the gaps identified in the disaster exercise; (6) update the emergency management plan based on the solutions delineated from the exercise; and (7) educate the staff on the updates made to the emergency management plan. This process is then repeated, with the new emergency management plan and individuals' response behaviors being evaluated. This process must be well documented for TJC and other regulatory agencies.

Responses to all types of mass casualty events require practice, whether they are natural disasters, bombings, response to victims of chemical terrorism, or mass vaccination programs in the face of a bioterrorism attack. By exercising different aspects of the emergency management plan, staff readiness for responding to any type of mass casualty incident can be assessed. The drills should address situations involving lack of electricity, water, or normal communications. Backup systems for each of these should be tested. Various scenarios should be used during disaster drills, including traditional, biological, and chemical terrorism scenarios as well as pandemics and natural disasters. It is also important to incorporate pediatric and other vulnerable population concerns during disaster exercises. These issues have historically been excluded from disaster drills but serve an important role in preparing a hospital for all types of mass casualty events.

The drills should also include decontamination strategies to help staff learn how to perform them more rapidly and correctly during an actual event. In addition, practicing decontamination procedure ensures that the facility has the equipment it will need.

Conclusions

Disasters and mass casualty events—whether caused by nature or man-made events—can have devastating consequences for public health and safety. IPs have a vital role in preparing for and responding to different types of mass casualty incidents. As experts in the fields of surveillance and epidemiology, they are responsible for investigating outbreaks and initiating interventions to prevent the transmission of infections before, during, and after mass casualty incidents. IPs must be familiar with the potential consequences of different types of mass casualty events, though they will follow the general principles of surveillance and epidemiology for each investigation and intervention. Advance planning and practicing of emergency management plans are essential to an effective response.

International Perspective

As the frequency of disasters and the number of people affected by such events has increased, disasters have become an international concern. This is especially true for mass casualty events resulting in an increase in infectious disease, such as a bioterrorism attack or pandemic. With the ease and frequency of international travel, it is conceivable for infectious diseases to have a major global impact. SARS and the 2009 H1N1 pandemic are good examples of this phenomenon. Many countries are working to improve emergency management strategies.

Due to the frequency of terrorist activity, Israel has developed many effective measures to rapidly and effectively handle mass casualty events. Israel credits frequent events and simulation exercises to their high level of preparedness and effective response.[25,26] Israeli hospitals practice all aspects of their

emergency management plans through up to 20 exercises or actual events per year.[26] Other effective interventions implemented by Israeli hospitals include (1) the use of written algorithms on cards and posters, (2) placing a staff member on the roof of the building to help direct patient flow, and (3) emphasizing disaster preparedness in all healthcare professionals.

Supplemental Resources

Many resources are available on emergency management. Please see the APIC website for disaster training opportunities: **http://www.apic.org/**.

Other website sources include the following:

USAMRIID. Available at: **http://usamriid.army.mil/**.

CDC. Available at: **http://www.cdc.gov/**.

Johns Hopkins Center for Biodefense. Available at: **http://hopkins-biodefense.org**.

Saint Louis University offers distance-based graduate degrees and certificates in biosecurity and disaster preparedness, including a specialized track in infection prevention. Information on these programs can be accessed at the following website: **http://www.biosecurity.slu.edu**.

In addition, many public health departments offer disaster educational opportunities; check with your local and state public health department(s) for further information.

Published: October 3, 2014

Abstract

Infectious disease disasters are events that involve a biological agent/disease and that result in mass casualties, such as a bioterrorism attack, a pandemic, or an outbreak of an emerging infectious disease. Infectious disease disasters are different from other types of disasters because they increase the risk of communicable disease spread during and after the incident. Subsequently, they involve the need for specialized mitigation, planning, and response interventions to prevent and control the spread of disease. As experts in the fields of surveillance, epidemiology, and prevention of communicable disease spread, infection preventionists play a critical role in emergency management of infectious disease disasters at the personal, hospital/healthcare facility, and community level. Emergency management of infectious disease disasters is a multidepartmental and multi agency endeavor that encompasses the four principles of emergency management: mitigation, preparedness, response, and recovery.[1]

Key Concepts

• Infectious disease disasters consist of biological terrorism, emerging infectious disease outbreaks, and pandemics.

• Infectious disease disasters pose unique challenges to infection preventionists and disaster planners.

• There are a broad range of potential bioterrorism agents, including bacteria, viruses, and toxins (of microbial, plant, or animal origin). Common characteristics of this diverse group of agents include:

oThe ability to be dispersed in aerosols of 1 to 5 micron-sized particles, which can penetrate the distal bronchioles

oThe ability to deliver these aerosols with simple technology

oThe feasibility of these agents, if delivered from a line source (e.g., an airplane) upwind from the target, to infect large numbers of the population

oThe ability to spread infection, disease, panic, and fear.

• Infectious diseases continuously emerge and/or reemerge, resulting in epidemics of varying sizes and scope.

• Pandemics pose the biggest potential threat to the public's health in terms of morbidity and mortality, and there is a high likelihood of a pandemic occurring in the future.

• Infection preventionists must undertake preparedness activities to ensure that they and their healthcare facilities and communities are better prepared to effectively recognize and respond to an infectious disease disaster.

• Infectious disease disaster preparedness is an ever-evolving process that addresses the four principles of emergency management: mitigation, preparedness, response, and recovery.

Background

DEFINITIONS OF BIOTERRORISM, EMERGING INFECTIONS, AND PANDEMICS

Bioterrorism (also known as biological terrorism) is the intentional use of a biological agent or derivative of such an agent to inflict harm or death onto a civilian population. Biological warfare differs from bioterrorism in that the target of the attack is military personnel. For the purposes of this chapter, the term *bioterrorism*will encompass both attacks on military and civilians using a biological agent/weapon.

Emerging infections are those that are new to a population or geographical region, or have increased rapidly. Many emerging infections, such as methicillin-resistant *Staphylococcus aureus*(MRSA) and human immunodeficiency virus (HIV), routinely occur throughout the world and are not covered in this chapter. Information on MRSA and HIV can be found in **26. Antimicrobials and Resistance**, and **81 HIV/AIDS**. Only newly emerging (infections that are new in humans) or reemerging infections (infections that occurred in the past but are now increasing in number or changing geographical area) are addressed in this chapter. For the purposes of this chapter, the term *emerging infection*is used in lieu of the terms *newly emerging*and *reemerging infections*.

Pandemics are global outbreaks of disease in humans that exceed expected rates or morbidity and mortality.

HISTORICAL PERSPECTIVE OF INFECTIOUS DISEASE DISASTERS AND FUTURE POTENTIAL IMPACT

Bioterrorism

The use of biological agents on populations to cause harm or death is not a new concept; countries have been conducting bioterrorism for hundreds of years. Bioterrorism dates back to the 14th century, when cadavers were dropped into enemy wells to poison the drinking water.[2]Another example of

bioterrorism occurred during the French and Indian War, when Native Americans were given smallpox-laden blankets. This action is believed to have initiated smallpox in this previously unexposed population and resulted in a 40 percent mortality rate. More recent examples of bioterrorism include the intentional contamination of salad bars in The Dalles, Oregon, using *Salmonella*[2] and the 2001 attack using anthrax-laden letters mailed to media organizations and politicians.

Bioterrorism has the potential to result in high morbidity and mortality, because aerosolized biological agents can infect or kill many people in a short period of time. Even nonaerosolized attacks, such as the anthrax bioterrorism attack in the United States in fall 2001, can result in morbidity, mortality, and the need to formulate a significant healthcare, public health, and emergency management response. It is not known when or if another bioterrorism attack will occur. However, bioterrorism preparedness helps mitigate potential negative outcomes, and is required by healthcare and public health regulating agencies as part of a comprehensive emergency management program.[3] The future potential impact of bioterrorism depends on the agent used, the amount disseminated, the dispersal method, the weather/release conditions, the preexisting immunity of the exposed population, and how quickly the attack is identified. The 2001 bioterrorism attack caused 22 cases of anthrax and five deaths, required over 10,000 doses of postexposure prophylaxis to be distributed, and cost more than $2.5 billion, yet was, essentially, a small event involving only the use of 2 to 3 ounces of anthrax spores.[4,5] Researchers estimating the potential morbidity, mortality, and cost associated with a bioterrorism attack indicate that an aerosolized release of *Francisella tularensis* over London could result in 2.4 million exposures, 130,000 infections, and 24,000 deaths, with an overall case fatality rate of ~18 percent.[6]

Emerging Infections

Emerging infectious disease outbreaks have occurred throughout recorded history. Examples include the Black Death in Europe, severe acute respiratory syndrome coronavirus (SARS CoV), West Nile Virus, 2009 H1N1 influenza A, Middle East respiratory syndrome coronavirus (MERS CoV), and many others. Many factors affect the emergence of infectious diseases, including social (war, human migration, and urbanization), microbial (genetic mutation, recombination, and assortment), and environmental (earthquakes, floods, deforestation, changes in animal/insect populations) determinants.[7,8]

The impact of emerging infections depends on the agent involved and the size of the event. For example, the 2012 multi-state outbreak of *Escherichia coli* 0145 was a relatively small event; 18 individuals were infected, with only a single death.[9] In contrast, the 2009 H1N1 influenza A virus developed into a pandemic, resulting in ~575,000 deaths.[10] The future potential impact of emerging infections is unknown, but it is expected that infectious diseases will continue to emerge or reemerge, resulting in epidemics of varying sizes and scope.

Pandemics

Of all types of infectious disease disasters, pandemics pose the biggest potential threat to the public's health in terms of morbidity and mortality. Historically, influenza pandemics occur on a semiregular basis. During the 20th century, three influenza pandemics (in 1918/1919, 1957/1958, and 1968/1969) resulted in more than 779,000 deaths in the United States and approximately 53 million deaths worldwide.[11] In 2009, a new strain of influenza A (H1N1) emerged and quickly became a pandemic, resulting in 151,700 to 575,400 deaths worldwide.[10] In addition, there have been several incidents in the

last 40 years in which an influenza strain had the potential of causing a pandemic, including scares or pandemic "threats" with swine, Russian, and avian influenza.[11]

The potential impact of a future pandemic is staggering. It has been estimated that an influenza pandemic could infect approximately 30 percent of U.S. citizens (~90 million individuals), require the need for 45 million additional outpatient visits to healthcare agencies and 865,000 to 9,900,000 hospitalizations, result in 89,000 to 207,000 deaths, and cost between $71 and $166 billion in the United States alone.[12,13,14]

As experts in the fields of communicable diseases, infection prevention, and epidemiology, infection preventionists (IPs) are poised to be at the forefront during an infectious disease disaster. As such, IPs must embrace their role as experts in infectious disease emergency management and assist their healthcare facility or community in becoming better prepared to rapidly, appropriately, and effectively respond to an infectious disease disaster.

Basic Principles

BIOTERRORISM

Bioterrorism refers to the use of biological agents on civilian or military populations, animals, or crops. A combination of factors have all raised concerns about the actual use of bioterrorism agents, including the breakup of the former Soviet Union and the concomitant dispersal of scientists and agents involved in bioterrorism research, the rise of radical groups focused on destroying what they believe to be evil forces, and the discovery of Iraq's stockpiled anthrax, botulinum toxin, and other biological warfare agents.

There are a broad range of potential bioterrorism agents, including bacteria, viruses, and toxins (of microbial, plant, or animal origin). Common characteristics of this diverse group of agents include (1) the ability to be dispersed in aerosols of 1 to 5 μm particles, which can penetrate the distal bronchioles; (2) the ability to deliver these aerosols with simple technology; (3) the feasibility of these agents, if delivered from a line source (e.g., an airplane) upwind from the target, to infect large numbers of the population; and (4) the ability to spread infection, disease, panic, and fear.[15]

The most likely route of dissemination is an aerosolized release of 1- to 5-μm particles. Other methods of dissemination include oral (intentional contamination of food/water supply), percutaneous, infected animal vector (e.g., release of infected fleas), and human-to-human spread (individual infected with communicable disease walking among a crowd of healthy people). As the anthrax attacks of 2001 proved, even physical objects, such as letters, can be used to help spread biological agents.

PANDEMICS

Unlike a bioterrorism attack or outbreak of an emerging infection, a pandemic is usually not an event that occurs suddenly. The World Health Organization (WHO) describes six phases of a pandemic, starting with the period in which there are few to no human cases from the organism/disease to the period in which there is efficient and sustained disease spread from person to person. The six WHO pandemic phases are outlined in Table 120-1. It is expected that a pandemic will hit communities in multiple waves. Each wave will last approximately 6 to 8 weeks, making response a more prolonged event than with other types of disasters.[12]During an influenza pandemic, attack rates will likely be about

30 percent across all populations; young children are expected to be disproportionately affected and have attack rates close to 40 percent.[12] It should be noted that not all pandemics will have a slow onset.

The 2009 H1N1 pandemic illustrated that a pandemic can occur suddenly and without warning.

Table 120-1 The Six Phases of a Pandemic

Phase	Description of the Phase
1	Low risk of human cases
2	Higher risk of human cases
3	No or very limited human-to-human transmission
4	Evidence of increased human-to-human transmission
5	Evidence of significant human-to-human transmission
6	Efficient and sustained human-to-human transmission

Adapted from World Health Organization (WHO). Current WHO phase of pandemic alert. WHO website. 2013. Available at: **http://www.who.int/influenza/preparedness/pandemic/h5n1phase/en/index.html**.

There are a number of agents that could cause a pandemic, including MERS CoV, SARS, and plague. Historically, influenza has caused the most pandemics and is expected to cause others in the future.[11]

Recent pandemic threats include H5N1 and H7N9, both avian strains of influenza A.

Nature of the Pandemic Threat

As of September 6, 2013, WHO indicates that we are in pandemic phase 3: There is an agent with the capacity to cause a pandemic (influenza A/H5N1), but there is currently no or very limited human-to-human transmission. As of August 2013, there have been 637 human cases of H5N1 avian influenza, 378 of whom have died.[16] As of August 22, 2013, there have been 135 cases of H7N9, 44 of whom died.[17] It is not known whether H5N1 and/or H7N9 will continue to mutate and adapt to become more easily spread from person to person, resulting in a pandemic. It is also possible that another strain or organism could emerge and cause a pandemic. A future influenza pandemic is considered inevitable, but it is not known what strain will be involved or when the event will occur.[12]

Preparedness For Infectious Disease Disasters

Many of the interventions needed to detect, prevent, and control infectious disease disasters are identical to those for other types of mass casualty events (see **119. Emergency Management**, for more information). However, infectious disease disasters pose unique challenges to IPs, healthcare and public

health agencies, response organizations, and businesses. These differences are discussed in this chapter.

Preparedness for infectious disease disasters begins at the personal level. This means that it is the responsibility of all IPs to have a personal/family emergency management plan that will enable him/her to continue working during the infectious disease disaster. For infectious disease disasters, this includes the need to have personal protective equipment (PPE) stored at home in case the need arises for its use in community settings.[18] The United States Department of Health and Human Services (DHHS) recommends that all families stockpile respiratory protection as part of their personal pandemic plan.[19]

See **119. Emergency Management**, for more information on personal emergency management plans.

It is critical for healthcare facilities to become better prepared for infectious disease disasters. Infectious disease disasters will result in a large number of patients requiring hospitalization for mechanical ventilation, isolation, or highly specialized treatment in intensive care beds. Studies indicate that most healthcare facilities do not have adequate resources or the infrastructure needed to manage all aspects of patient care during an event that lasts longer than a few days, let alone the 6 to 8 weeks that may be necessary during a pandemic.[3] Deficiencies in hospital preparedness for infectious disease disasters include a lack of ventilators, antibiotics or antiviral medications, respiratory protection (N95 respirators and masks), negative pressure rooms/areas, laboratory support/supplies, and linens.[3,20] Two studies conducted during the early part of the 2009 H1N1 pandemic found that many U.S. hospitals lacked infection prevention supplies, including respirators and anti-infective therapy.[20,21] Another study reported that almost a quarter of all U.S. hospitals lack 24/7 infection prevention coverage, which would make responding to an infectious disease disaster very challenging.[3]

At the community level, it is vital that healthcare agencies become better prepared for infectious disease disasters. Hospital surges during an infectious disease disaster will trickle down into community healthcare services and cause response challenges for these agencies. Potentially contagious patients will likely be discharged to alternate care sites, long-term care, and home care during an infectious disease disaster, requiring the need for surge capacity and infection prevention strategies/programs in these settings. Despite this, a 2010 study conducted during the H1N1 pandemic found that almost a third of all home health agencies lack any surge capacity, which would not allow hospitals to discharge patients to home health as planned.[22] Infection prevention strategies described in this chapter apply to all settings that administer healthcare services.

IPs play an important role in becoming prepared for infectious disease disasters at the personal, facility, and community levels. Preparedness activities must be undertaken by IPs to ensure that they and their healthcare facilities and communities are better prepared to effectively recognize and respond to an infectious disease disaster. As experts in infectious diseases, infection prevention, and epidemiology, IPs play a critical role in helping healthcare facilities/agencies and communities become better prepared to recognize and respond to an infectious disease disaster.

Infectious disease disaster preparedness is an ever-evolving process that addresses the four principles of emergency management: mitigation, preparedness, response, and recovery.[23] In addition, preparedness means that individuals and facilities develop an emergency management plan, practice the plan, and evaluate their level of preparedness. IPs must become better prepared not only to personally recognize and respond to an event but also to aid their healthcare facilities/agencies and communities in doing the same.

ASSESSMENT

Assessment is the first step in preparing a healthcare facility, healthcare agency, or community for an infectious disease disaster. Facility, agency, and community assessments are multidepartmental, multi agency endeavors that should not be undertaken alone. Information on emergency management plan assessment may be found in **119. Emergency Management**.

PLANNING FOR INFECTIOUS DISEASE DISASTERS

Emergency management plans must address all hazards, including infectious disease disasters. For most hospitals and healthcare agencies, this will mean having an annex or section of their emergency management plan that is specific to infectious disease disasters.

Various planning guides exist to aid in preparing for infectious disease disasters, and each is aimed at a specific group/agency. For example, the Pandemic Influenza Plan written by the DHHS is designed to be used by local and state disaster planners and public health departments.[24]

In 2009, a planning checklist was developed for hospitals to assess the infection prevention components of their emergency management plan.[25]Emergency medical services (EMS) agencies can obtain guidance from the DHHS in the Emergency Medical Services and Non-Emergency (Medical) Transport Organizations Pandemic Influenza Planning Checklist.[26]In 2012, Volkman et al.[27]published a guidance document for long-term care facilities to use when developing emergency management plans, including addressing planning for bioterrorism and pandemics. A planning checklist was published in 2011 that describes the infection prevention components needed in a home health agency emergency management plan.[28]In addition, DHHS has published a number of pandemic planning checklists for businesses, schools, and faith-based organizations.[29]

The above are just a few examples of planning guides for infectious disease disasters. Other documents are available through state health departments and healthcare agencies.

IDENTIFICATION OF AN INFECTIOUS DISEASE DISASTER

Morbidity and mortality related to many agents that could be involved in an infectious disease disaster can be decreased if treatment, isolation, and prophylaxis are provided as soon as possible. A rapid response depends on the foundation of the plan that is in place before the event occurs and the participants' familiarity with the emergency management plan.

When even a single case of an unusual disease is suspected or identified, bioterrorism or an emerging infectious disease should be considered. Groups of nonspecific illnesses clustered in time or place should also be strongly considered for bioterrorism or an outbreak of an emerging infectious disease. This includes the clustering of flulike syndrome in patients. All cases of unusual disease, including even a single case of any of the diseases mentioned in this chapter, should be reported immediately to local public health officials; if cases are recognized during evenings or weekends, after-hours or emergency numbers should be used.

Specific diagnosis of the agents discussed in this chapter has historically relied heavily on the presence of appropriate epidemiologic exposure (e.g., exposure to infected animals during meat rendering for anthrax, ingestion of home-canned foods for botulism, or travel to an area where an emerging infectious disease is endemic). Dissemination of biological agents via an aerosol route will require diagnosis of these generally uncommon diseases without the aid of usual exposure history. Furthermore, many of

these syndromes can only be diagnosed on the basis of clinical knowledge of presenting symptoms and expected disease progression. Maintaining a high level of suspicion and clinical knowledge about these diseases is essential to timely diagnosis. Assays/tests for bioterrorism agents and emerging infectious diseases are often only available in specific research laboratories (state public health laboratories, Centers for Disease Control and Prevention [CDC], or United States Army Medical Research Institute of Infectious Diseases [USAMRIID]); consult your local/state health department to arrange for appropriate testing or for consultation.

EARLY RECOGNITION OF AN INFECTIOUS DISEASE DISASTER

IPs may be the first to detect an infectious disease disaster, and early detection decreases morbidity and mortality. The sooner the incident and at-risk patients are identified, the higher the likelihood of decreasing morbidity, mortality, and cost associated with the event. The difference between infectious disease disasters and other mass casualty events is that infectious disease disasters are more difficult to detect. With natural disasters, and even traditional or chemical terrorism, there is an obvious sign that something unusual has happened. This can range from damaged buildings in an earthquake to a huge influx of patients immediately after a chemical attack.

In a bioterrorism event, however, an explosion is unlikely, and we may not know that there has been an attack unless the perpetrators announce it (i.e., it is an overt event), because aerosolized biological particles are odorless, colorless, and tasteless. In the case of a covert bioterrorism attack, a few days or weeks after the release, patients will begin to show symptoms and will access the medical system at that point. These patients will probably go to an emergency department or some other primary care facility. Detection will be difficult because it is unlikely that all the patients will go to the same facility or primary care provider. In this scenario, surveillance is essential to early detection of the event.

Like a bioterrorism attack, an outbreak of an emerging infectious disease may be difficult to detect. Clinicians rarely see these diseases, and the outbreak could even involve a novel strain or organism, making diagnosis very difficult. If the outbreak involves a new organism, such as the appearance of the coronavirus that causes MERS (MERS Co-V) in 2012, there may not be a laboratory test readily available for confirmation testing. Surveillance will be essential to detect a new outbreak and identify new cases once an outbreak is underway.

Early identification of a pandemic will be easier than that for bioterrorism or an outbreak of an emerging infectious disease. This is because pandemics tend to occur gradually over time, following the phases identified by WHO (see Table 120-1 for a list of the six WHO pandemic phases).[12] However, even pandemics can occur quite suddenly, as was the case with the 2009 H1N1 influenza A pandemic.[21] As the threat of a pandemic rises, IPs should continue to communicate with public health officials regarding the current status of the event.

Early recognition of an infectious disease disaster can occur by one of two methods: passive or active surveillance. See **11. Surveillance**, for more information on surveillance.

Passive surveillance for infectious disease disasters refers to clinicians maintaining a high index of suspicion for potential diseases caused by bioterrorism or unusual disease presentation that may signal an emerging infectious disease. Clinicians who suspect bioterrorism may have occurred or an emerging infectious disease must report this incident to the infection prevention/infectious disease department and local health department immediately.

Active surveillance refers to surveillance activities implemented to detect bioterrorism incidents or other infectious disease disasters. However, emerging infectious diseases and most of the potential bioterrorism agents cause uncommon illnesses, such as inhalational anthrax, tularemia, monkeypox, and MERS CoV, and most facilities do not have the laboratory capability to test for these agents. This makes case finding very difficult.

An example of an active surveillance program would be one in which the data collector would contact specified people or groups in the community and ask for predetermined information or collect such information from hospitalized patients. Traditional active surveillance involves the collection of clinical information, usually in the form of laboratory tests, but can include other relevant clinical data such as chest radiograph results and patient symptoms. It is not feasible to conduct active surveillance using laboratory tests to detect an infectious disease disaster because there are too many possible causative agents. A study by Kaplan[30]examined the feasibility of conducting surveillance for bioterrorism using blood donation samples tested for a series of bioterrorism-related agents (e.g., anthrax, plague), just as donated blood is routinely tested for HIV and hepatitis. This study found that not only would detection of the event be delayed using this type of surveillance methodology, but it would also be prohibitively expensive. To screen all blood donations for bioterrorism-related agents would cost approximately $10/donor, totaling $139 million per year.[30]

BIOWATCH

BioWatch is an environmental monitoring program that is managed in coordination by the CDC, Environmental Protection Agency (EPA), and the United States. Department of Homeland Security. This program uses air samplers to test for aerosolized biological agents around the United States, with the goal of rapidly identifying biological events. Rapid detection of an infectious disease disaster would help minimize morbidity, mortality, and costs. The BioWatch air samplers are located in undisclosed cities and monitor the air 24 hours a day, 7 days a week. The specimens collected by BioWatch are sent to the Laboratory Response Network (LRN) and tested for various agents. When biological particles are detected in the air, a report is sent to emergency managers and public health professionals in the communities in which the agents were detected. These reports are termed "BioWatch Actionable Results" (BARs). Communities must decide how to respond to these BARs in terms of the extent to which an investigation is conducted or interventions are implemented.

Although BioWatch has not detected a single bioterrorism attack (because no aerosolized attacks have occurred since the start of the program), BioWatch has been credited with strengthening the United States' existing biosurveillance program and enhancing coordination between public health agencies and healthcare systems as a means of increasing community resilience.[31]BioWatch is currently considered a complementary system to existing biosurveillance programs established in communities.

SYNDROMIC SURVEILLANCE

Instead of conducting traditional active surveillance to detect an infectious disease disaster, a different approach must be used. Active surveillance for infectious disease disasters involves the use of syndromic surveillance. Historically, syndromic surveillance referred to the collection and analysis of syndrome-related data. A few examples of traditional syndromic surveillance indicators include (1) severe flulike illness indicating a new emerging pathogen (e.g., MERS CoV), pandemic influenza, or a bioterrorism attack involving the release of *Bacillus anthracis*(inhalational anthrax), *Yersinia pestis*(pneumonic plague), variola (smallpox), or other agents; (2) flaccid muscle paralysis indicating that a neurotoxin, such as botulism toxin, may have been released; (3) bleeding disorders indicating the use

of a viral hemorrhagic fever agent; (4) rash indicating the release of variola virus (the cause of smallpox); or (5) gastrointestinal (GI) symptoms that present similarly to food- and waterborne illnesses, possibly indicating an intentional release on a water or food source or vendor.

The concept of syndromic surveillance has evolved over time to encompass more than simply syndrome-related data. It now consists of collecting and analyzing any nontraditional data for early detection of an infectious disease disaster. Syndromic surveillance now includes any indicator that might signal an increase in illness in the community. Some examples of data that could be collected and analyzed as part of a syndromic surveillance program include (1) number of patients seen in an emergency department; (2) number of patients presenting to the emergency department with flulike illness as their chief symptom; (3) number of patients admitted to a hospital; (4) number of EMS or ambulance runs performed each day, week, month, or other time period; (5) number of purchases of over-the-counter flu remedies; (6) number of purchases of over-the-counter diarrhea medications; or (7) other data available from healthcare facilities or agencies that may indicate a change or trend in the community. In studies, International Classification of Diseases Ninth Revision (ICD-9) codes and GI syndromes have high sensitivity and specificity in syndromic surveillance, whereas respiratory syndromes, chief symptom as an indicator, and fever alone were less sensitive measures. A 2011 study by Bellazzini and Minor[32]found that emergency department syndromic surveillance indicators, such as chief complaint or ICD-9 diagnostic codes are significantly faster at identifying an upward trend compared to laboratory-based data. Medication sales have been found to be useful indicators when used in conjunction with clinical syndrome indicators.[33]Combining multiple indicators has been found to yield the most accurate and sensitive information during syndromic surveillance, but can be expensive and resource intensive.[34,35]

Some communities are now collaborating with veterinarians and incorporating animal and insect surveillance data in the community syndromic surveillance program. Animal syndromic surveillance is important because more than 60 percent of human emerging infectious diseases are zoonotic;[36]an infectious disease outbreak among animals may be the precursor to human illness in a community. Animal syndromic surveillance began with cattle and livestock surveillance, but has expanded over time into also collecting data on companion animals. Examples of animal syndromic surveillance indicators include cattle mortality rates at farms and rendering plants, the number of visits at animal hospitals, and the number of laboratory tests requested by veterinary clinics, regardless of the results.[37]An innovative approach to public health syndromic surveillance is to combine animal and human data indicators. By doing this, it increases the sensitivity and specificity of the syndromic surveillance data being analyzed. Examples of parallel syndromic surveillance data indicators that have been collected include the following: (1) rate of influenza-like illness (ILI) in humans and in domestic cats, and (2) number of emergency room visits per day or per week at human and animal hospitals.[37]

Syndromic surveillance indicators must be evaluated in relation to facility and community illness baselines and current trends. Any upward trend or sharp increase must be evaluated as soon as possible to determine if an infectious disease disaster has occurred.

Syndromic surveillance data collection and analysis must be a component of facility and community emergency management. It should be a multiagency endeavor, including coordination and communication between hospitals, healthcare agencies (long-term care, home health), and public health.

Table 120-2 outlines syndromic surveillance indicators that healthcare facilities, schools, businesses, and veterinary clinics may consider collecting as part of their syndromic surveillance program for infectious

disease disasters. All healthcare agencies, including long-term care and home health, should consider conducting syndromic surveillance. In addition, public health officials should consider partnering with schools and businesses to collect syndromic surveillance data, such as absenteeism rates related to ILI. Many syndromic surveillance programs exist (a 2004 study identified 115 such systems).[38] Facilities and agencies will need to decide which program or indicators work best for them. The CDC indicates that all hospitals should implement, at the least, a syndromic surveillance system that identifies patients with ILI; recommended sites for implementing this surveillance program include the emergency department, hospital clinics, and occupational health.[39] Syndromic surveillance programs should be coordinated with local public health agencies to provide consistency in data collection and ensure adequate coverage across regions.

Table 120-2 Syndromic Surveillance Indicators

Indicator
Flu like illness*
Flaccid muscle paralysis
Severe bleeding disorder with no discernable source
Rash
Gastrointestinal symptoms
Number of patients seen in an emergency department
Chief symptom (i.e., number of patients presenting with flulike illness as their chief symptom)
Number of patients admitted to a hospital
Number of EMS or ambulance runs
Number of calls to nurse or physician help lines triage centers
Over-the-counter pharmaceuticals sales (i.e., nonprescription medications to treat flu or gastrointestinal symptoms)
Number of individuals who use an Internet search engine (e.g., Google or Yahoo!) to look up information about flulike symptoms
Cattle or livestock morbidity or mortality rates
Domestic animal morbidity or mortality rates
Number of laboratory tests conducted at veterinary clinics
School absenteeism rates
Staff absenteeism rates at local businesses
*The CDC indicates that all hospitals should implement, at the least, a syndromic surveillance system that identifies patients and staff with influenza-like illness.[39]

BioSense

BioSense is a national syndromic surveillance program for the United States that is run by the CDC. BioSense allows healthcare and public health agencies to quickly access and share data across regions or the nation. It was originally designed to assist with rapid identification of a bioterrorism attack but also has the opportunity to recognize an outbreak of an emerging infectious disease or pandemic,

allowing for a more rapid response to the event. Data for BioSense derives from at least hundreds of hospitals, multiple state syndromic surveillance programs, and thousands of pharmacies and laboratories across the United States.[40]Most data submitted to BioSense are sent in real time, but a few sources have delayed reporting. BioSense tracks data by categorizing it into syndromes, such as ILI. Similar to other surveillance programs, spikes in BioSense data necessitate an investigation to determine whether it is a false alarm or a true infectious disease outbreak/anomaly. Most spikes in indicator rates result from predicable variation, inaccurate information provided to BioSense, misclassification of data, short-term anomalies, or a change in the community that is unrelated to an outbreak (e.g., a sale on over-the-counter pharmaceuticals that prompts increased sales). If the data spike is determined to be a potential legitimate threat, the CDC contacts the community from which the data derived to do an in-depth analysis. This may necessitate the involvement of hospitals, healthcare agencies, and local public health authorities to determine the source of the data anomaly. Although BioSense did not help in identifying the 2009 H1N1 pandemic, BioSense data was used by the CDC Emergency Operations Center and CDC's Influenza Division to determine H1N1 vaccine prioritization schedules, inform decisions related to school and public building closures, and aid in assessing the overall severity of the pandemic in the United States.[40]Between 2010 and 2012, BioSense data was used to monitor the impact of the 2010 Gulf of Mexico oil spill, enhance surveillance for dengue, and assess the health impacts related to the 2011 Japanese tsunami and subsequent nuclear incident as well as the 2011 U.S. heat wave.[40]BioSense data has also been used to enhance hospital epidemiology studies, including studies examining healthcare-associated pneumonia and *Clostridium difficile*.[41,42]

VULNERABLE POPULATIONS

Certain groups of individuals are more at risk from morbidity and mortality during an infectious disease disaster. These individuals are known as vulnerable populations. Meeting the needs of vulnerable groups must be addressed as part of infectious disease disaster planning and included in the emergency management plan at the facility and community level. General disaster planning for vulnerable populations is covered in **119. Emergency Management**. Only issues that are specific to infectious disease disasters are covered in this chapter.

Pediatrics

Children, especially newborns and young children are at an increased risk for infection during most types of infectious disease disasters. Neonates may be at risk from infection during an infectious disease disaster in two ways: vertical transmission from the mother during pregnancy and healthcare-associated transmission after birth.[43]Although newborns may be provided some protection by passive immunity (receipt of antibodies from the mother while in utero), they may be susceptible to certain diseases if the mother develops an infection during pregnancy. Neonates are also more at risk from infection than adults and even older children because of their relative state of immunosuppression, which predisposes them to many types of infections. Babies who are born prematurely are also at high risk from a variety of infections.

During a bioterrorism attack involving the release of an aerosolized agent, children are at higher risk from exposure than adults because of children's increased respiratory rate, which would result in their inhalation of more infectious particles.[44]In addition, newborns and young children have more permeable skin than adults, increasing the risk of toxin absorption through the skin.[44]Children are also at higher risk during a smallpox bioterrorism incident because they have never been immunized against variola. Although most adults do not have active immunity against smallpox because their initial immunization

was more than 30 years ago, individuals who receive a booster of smallpox vaccines (i.e., most adults born before 1972) are much more likely to have a sustained immune response compared with primary vaccinees (i.e., children). In addition, children infected with smallpox are more likely than adults to be misdiagnosed with chickenpox because of the increased incidence of this disease in children. Children are also expected to be at higher risk of infection and fatality during an influenza pandemic.[12]

Attending school or a childcare agency also puts infants and children at increased risk for infection during biological events. Research indicates that schools and childcare agencies are often associated with communicable disease spread among children.[45,46]Epidemiological studies indicate that school openings have been associated with spikes in cases during outbreaks and pandemics, including the 2009 H1N1 pandemic, and school closure (whether intentional event-specific closure or natural closure due to breaks/holidays) is associated with sudden drops in cases.[47,48]Close interaction at school or childcare puts children at risk from disease spread unless control measures are implemented.

Elderly

The number of elderly individuals in the United States is growing, and the fastest growing group among the elderly are those who are 85 years or older. Normal declines in physiological function that occur with aging put the elderly at higher risk for infection. In addition, many older adults have comorbidities, which put them at higher risk for infection at all times, and this risk can be magnified during an infectious disease disaster. Infectious diseases currently account for 40 percent of deaths among the elderly, and rates are expected to be even higher during a pandemic or bioterrorism attack.[49]

Diagnosing infectious diseases among the elderly can be complicated. Most elderly individuals have a pulse/temperature dissociation that masks the signs of infection, making diagnosis much more difficult in the elderly than in adults or children.[49]Therefore, triaging algorithms need to take this pulse/temperature dissociation into account and use a lower temperature as a potential indicator of infection among the elderly (see "Triage" section of this chapter). In addition to having a pulse/temperature dissociation, the elderly commonly have atypical disease presentation because of normal organ system changes and comorbidities. These factors can make diagnosis of infectious diseases very difficult among the elderly, especially during an infectious disease disaster.

Immunocompromised

Immunosuppression results in an increased risk for infectious disease, even during nondisaster times. Immunocompromised individuals can be expected to have increased complications and mortality rates after an infectious disease disaster compared with healthy adults.[50]Immunocompromised individuals with comorbidities are at an increased risk.

Very little is known about bioterrorism-related disease presentation in immunocompromised hosts, but it is believed that these individuals will likely have unusual disease presentation, which will complicate and possibly delay diagnosis.[50]In addition, disease is expected to be more severe for immunocompromised patients during an infectious disease disaster compared with healthy adults, especially among patients with HIV and cancer.

Pregnancy

Normal physiological changes during pregnancy, such as a somewhat compromised immune system, decreased ventilatory capacity, and increased respiratory tract bacterial growth, put women at an

increased risk for disease.[43] Influenza infection during pregnancy may cause poor outcomes, such as longer hospital stays, more frequent hospitalization not related to delivery, and maternal death.[43] These risks were amplified in past pandemics and are expected to hold true during future influenza pandemics.[12] Mortality rates were higher for pregnant women than for nonpregnant individuals during the 1918 influenza pandemic, and influenza was the leading cause of maternal death in the 1957 pandemic.[43]

Pregnant women are also at higher risk for fatality during outbreaks of emerging infectious diseases and bioterrorism; mortality rates were higher for pregnant women than for nonpregnant individuals during the SARS outbreak in 2003 and during past smallpox outbreaks.[51]

Fetuses are at risk from infection and death while the mother is pregnant. Infections women develop during pregnancy, such as SARS or smallpox, can lead to spontaneous abortion or preterm birth.[43] In addition, many medications or vaccinations that might be needed during an infectious disease disaster to treat or prevent disease in pregnant women could cause potential harm to the fetus.[52] Examples include smallpox vaccination and live attenuated vaccines.[52]

Some women with high-risk pregnancies will require specialized care/treatment while in labor and delivery, even during an infectious disease disaster. However, most women with normal pregnancies may be better served by giving birth in an alternate care site or the home to prevent exposure to communicable diseases during an infectious disease disaster.[52] Communities will need to make arrangements for continuing to provide prenatal care, labor and delivery services, and newborn care in the community during infectious disease disasters as part of emergency management.[52] Hospitals and healthcare facilities need to develop triaging algorithms for determining which women require hospitalization and which can be managed in another setting.[52] During the 2003 SARS outbreak in Canada, pregnant women delivered their babies in nonhospital settings as a way of physically separating pregnant women from potentially contagious patients; this was effective at decreasing disease transmission during labor and delivery.[43]

REPORTING INFECTIOUS DISEASE DISASTERS

All cases of unusual disease or syndrome clusters should be reported immediately to local public health officials, including even a single case of any of the diseases mentioned in this chapter. If cases are recognized during evenings or weekends, after-hours or emergency numbers should be used. Phone trees should be developed as part of emergency management planning to ensure that reporting can take place around the clock. Staff should be educated to report any known or suspected patients with bioterrorism-related diseases or an emerging infectious disease to the infection prevention, infectious disease, and/or hospital epidemiology department(s). During an infectious disease disaster, reporting should occur through the facility incident command system (see **119. Emergency Management**, for information on the hospital incident command system).

EPIDEMIOLOGY OF BIOTERRORISM OR OUTBREAK OF AN EMERGING INFECTIOUS DISEASE

It is difficult to predict and delineate the epidemiology of a bioterrorism attack or emerging infectious disease outbreak before it occurs, but the general principles of epidemiology, infection prevention, and

outbreak investigation apply. An outbreak investigation may be warranted if a communicable disease is involved or epidemiological information, such as risk factor data, needs to be collected and analyzed.

In the event of an unannounced bioterrorism attack, the epidemiological investigation will be critical to mounting an effective response. If terrorists covertly release an aerosolized biological weapon, the event will not be detected until days to weeks after the incident, when patients become ill and begin infiltrating the medical system. When this occurs, a rapid and focused epidemiological investigation will be needed to identify the possible date and location of the release. Victims' histories will be taken and examined for shared activities, such as attendance at a mutual event. It is essential that the release date and location be identified to determine other people/groups who are potentially at risk. This information can guide distribution of treatment, prophylaxis, and vaccination.

If a contagious agent is used in a bioterrorism attack, the epidemiological investigation will be even more critical. Not only will the date and location of release need to be identified, but a list of contacts (i.e., people who came into contact with infected patients since the onset of infectiousness) must be identified as well. For instance, if smallpox is released as a biological weapon, there are two distinct groups at risk of exposure: (1) those exposed to the initial release (which will be identified when the date and location of the release is determined) and (2) those exposed to infected individuals during periods of contagiousness (which will be identified in a thorough epidemiological investigation of potential contacts). These same principles will apply if the infectious disease disaster is an outbreak of a contagious emerging pathogen, although the source or potential vector may need to be identified rather than a release point.

As with any outbreak or epidemiological investigation, the three primary factors of contextual concern are person, place, and time. The basic information that will need to be determined as soon as possible after a bioterrorism attack or outbreak of an emerging infectious disease is detected includes the following: (1) identification of the causative agent, (2) establishment of the case definition, (3) determination of date of release, (4) location of release, (5) assessment of the approximate length of exposure time, and (6) determination of the potentially exposed groups. The response to an infectious disease disaster will depend on the answers to these questions. If a contagious agent (e.g., aerosolized plague or smallpox) was involved, the epidemiological investigation will be quite different from an investigation if a noncontagious agent (e.g., anthrax) was involved. In addition, the date, location, and approximate length of exposure time will affect the response needed. The epidemiological investigation and necessary response will be different for a small release in a contained area versus a large release in an open area or if the outbreak involves an insect or animal vector.

Causative Agent Identification

Regardless of whether the infectious disease disaster is a bioterrorism attack or outbreak of an emerging pathogen, it will be imperative to establish the causative agent as quickly as possible. Treatment, prophylaxis, and control measures all depend on the causative agent. Time is of the essence because patients with diseases caused by some of these agents can progress to death very rapidly without appropriate treatment. For example, untreated pneumonic plague usually progresses to death within 36 to 72 hours.[53]Although diagnosis will not be a direct responsibility of the IP, it is likely that the IP's infectious disease expertise will be consulted in the evaluation process and in deciding which, if any, isolation precautions should be implemented while awaiting confirmatory diagnosis.

Agent identification and patient diagnosis will depend a great deal on the effectiveness of the passive surveillance system used by the facility or agency. If clinicians have maintained a high index of suspicion

and have a good knowledge foundation regarding the potential diseases that could be involved in an infectious disease disaster, it is more likely that the event/outbreak will be rapidly identified.

Identification of the Date and Location of Agent Release or Potential Source of Pathogen

An IP's epidemiological skills will be necessary to identify when and where the release of the biological agent(s) occurred, or the source/vector of an emerging pathogen. The date and location of release or potential source are critical to determine at-risk groups, control measures, and, depending on the agent, may determine who needs to be vaccinated and/or receive prophylaxis. To determine when and where the exposure took place, a thorough patient history of any and all victims of the bioterrorism attack must be taken. This history should focus on (1) past and current symptoms, (2) date of symptom onset, (3) severity of illness, (4) possible source of exposure, (5) route of exposure (body site affected), and (6) date and location of exposure. For example, a new painless necrotic lesion on the arm might indicate cutaneous anthrax, whereas respiratory symptoms with an accompanying widened mediastinum on chest radiograph would suggest inhalational anthrax. Both diseases result from exposure to the same agent, but the route of exposure is different.

Determining the source of exposure may be the most challenging component of the epidemiological investigation. However, it will also be one of the most critical components because it will help determine at-risk groups that might benefit from prophylaxis or vaccination. Determining the date and location of the exposure will be aided by listing all the places the patient had been during the incubation period of their illness; a travel history will be an essential component. The time period for which a history needs to be collected (i.e., the incubation period) will depend on the agent used; this time period can range from 1 day to weeks before symptom onset. If the date and location of release can be quickly determined and at-risk persons identified, a targeted prophylaxis or vaccination program can be initiated. If the date and location cannot be rapidly determined, consider mass prophylaxis or immunization to protect the community at large. Occupational risk exposures should also be assessed, especially if the person is a laboratory, healthcare, or sanitation professional, or if the person works with animals (e.g., in a veterinary clinic, meat rendering plant, or poultry or swine farm).

Potential Bioterrorism Agents

The CDC provides a list of the most likely agents to be used in a bioterrorism attack. These agents are divided into three categories (A, B, and C) with category A agents being the most likely to be used.[15]

Table 120-3 reviews the most likely agents of bioterrorism.

Table 120-3 Centers for Disease Control and Prevention Bioterrorism Agents

Category A
Anthrax (*Bacillus anthracis)*
Botulism (*Clostridium botulinum toxin*)
Plague (*Yersinia pestis*)
Smallpox (variola major)
Tularemia (*Francisella tularensis*)
Viral hemorrhagic fevers (filoviruses [e.g., Ebola, Marburg] and arenaviruses [e.g., Lassa, Machupo])
Category B

Brucellosis (*Brucella species*)
Epsilon toxin of *Clostridium perfringens*
Food safety threats (e.g., *Salmonella species, Escherichia coli*O157:H7*, Shigella*)
Glanders (*Burkholderia mallei*)
Melioidosis (*Burkholderia pseudomallei*)
Psittacosis (*Chlamydia psittaci*)
Q fever (*Coxiella burnetii*)
Ricin toxin from *Ricinus communis*(castor beans)
Staphylococcal enterotoxin B
Typhus fever (*Rickettsia prowazekii*)
Viral encephalitis (alphaviruses [e.g., Venezuelan equine encephalitis, eastern equine encephalitis, western equine encephalitis])
Water safety threats (e.g., *Vibrio cholerae, Cryptosporidium parvum*)
Category C
Emerging infectious diseases such as Nipah virus and hantavirus
Adapted from Centers for Disease Control and Prevention (CDC). CDC bioterrorism agents. CDC website. 2013. Available at: **http://emergency.cdc.gov/agent/agentlist-category.asp**

Clinical Manifestations of Bioterrorism-related Diseases or Emerging Pathogens

The diseases produced by bioterrorism agents could be incapacitating or lethal. Because these agents would most likely be released via an aerosol route, resulting in pulmonary infection, many of the clinical syndromes include a febrile syndrome with accompanying respiratory symptoms. Agents causing GI symptoms (e.g., nausea, vomiting, and diarrhea) are also likely to be used, and have been used in past bioterrorism attacks.[2]Other possible clinical syndromes related to bioterrorism include fever with a centrifugal rash (smallpox), a rapidly descending flaccid muscle paralysis (botulism), or a severe bleeding disorder (viral hemorrhagic fever virus).[53]

Emerging infectious diseases can demonstrate a variety of clinical manifestations, from ILI to GI disorders. Many emerging infectious diseases can be expected to be zoonotic in nature.[36]The exact clinical picture of an emerging infectious disease will be specific to the pathogen.

TRIAGE AND SCREENING

Triage is an important component of emergency management to quickly identify those individuals who need medical treatment first. Severely ill or injured patients need to be transferred to a medical facility as soon as possible. During an infectious disease disaster, triage involves assessment for not only disease/injury severity, but also screening for potential contagiousness. Patients and visitors may need to be screened before they are allowed entry into healthcare facilities, points of dispensing or distribution (PODs), or alternate care sites (ACS). Healthcare personnel may need to be screened before each shift, depending on the event and the associated morbidity and mortality. Table 120-4 is a generic assessment/screening form that can be used to identify potentially contagious individuals during

an infectious disease disaster. This table/tool would need to be modified to be event-specific during an infectious disease disaster; screening items should be based on the case definition for the disease/condition involved in the incident. For example, a screening tool for MERS CoV might include a question related to a recent travel history to an area in which cases of MERS CoV have occurred.

Healthcare facilities, PODs, and ACS should encourage informal screening of patients, visitors, and staff for potentially contagious conditions/diseases. Posters describing signs and symptoms that should be reported to healthcare personnel should be strategically located around the facility.

Table 120-4 Sample Generic Screening Form for Infectious Disease Disasters

Screening/Triage Form*

Association of Professionals in Infection Control and Epidemiology website. 2013. Available at: http://apic.org/Resource_/TinyMceFileManager/Emergency_Prep/2013_Ambulatory_Care_during_Disasters_FINAL.pdf.

Screening Area

If formal screening is to be conducted during a biological disaster, a screening area will need to be set up. Research indicates that it is most effective to limit the number of formal screening areas (to maximize available resources) by locking off extra entrances during the infectious disease disaster, provided that fire and safety codes are not violated by doing so.[21] The screening area should be set up either outside or immediately inside the entrance to the healthcare facility, and it should be manned by a trained screener. The screening area should have hand hygiene and PPE available for the screener(s) and visitors.

Potentially contagious individuals identified through screening should be moved immediately to an isolation room/area. A temperature of 100°F should be used as the identifier for potential infection to identify the elderly or immunocompromised individuals whose physiological changes tend to mask normal signs of infection.[49]

ANTI-INFECTIVE THERAPY, PROPHYLAXIS, AND VACCINATION

Several of the potential bioterrorism agents and emerging infectious diseases have effective treatment regimens, when such therapy is initiated early in the disease process. Immediate recognition of the disease process and rapid administration of appropriate treatment modalities are essential to decreasing the morbidity and mortality of an infectious disease disaster.

In most situations, chemoprophylaxis will be important during an infectious disease disaster. Several of the bacterial and viral agents of bioterrorism have effective postexposure prophylaxis (PEP) available in the form of either medical treatment or vaccination. Some emerging infectious diseases, such as pandemic influenza, also have identified PEP regimens. Exceptions to the need for PEP would be diseases for which there is no known effective prophylaxis available, such as viral hemorrhagic fever, SARS, or MERS CoV. PEP should be offered to all those with a known exposure to a potentially contagious patient/person. This includes patients, visitors, staff, and volunteers. Immediate recognition of the disease involved in the infectious disease disaster and clearly defining the population exposed will be crucial for dispensing appropriate PEP to those most at risk. Information on what constitutes an exposure and contact tracing are part of the epidemiological investigation and should be coordinated with local public health officials. PEP should be offered as soon as an exposure is suspected. Delayed PEP can decrease effectiveness of the medication or vaccine and result in increased morbidity and mortality.

The DHHS currently recommends that communities and healthcare facilities consider offering preexposure prophylaxis to high-risk healthcare personnel (those with direct high-risk exposures) and front-line workers (emergency department workers, first responders, EMS personnel) during a pandemic.

[54]Preexposure prophylaxis would consist of taking antiviral medications for the duration of the outbreak in the community. This strategy is expected to decrease disease transmission among the highest risk individuals and allow these groups to continue working during a pandemic by preventing illness associated with the event. Preexposure prophylaxis will require large numbers of doses of medication (a 6- to 12-week regimen/provider); the decision to allocate medication to preexposure prophylaxis needs to be examined in light of the facility's ability to provide ongoing PEP and treatment. Treatment and PEP are higher priority than preexposure prophylaxis, and this needs to be incorporated into healthcare facility/agency prioritization plans.[54]If a healthcare facility/agency's supplies of antiviral medications start to dwindle, even if supplemented from the CDC's Strategic National Stockpile (SNS), medications need to be reserved for treating cases and providing PEP.

Vaccination can be an important component of responding to an infectious disease disaster, depending on the agent/disease involved in the event. For some diseases/agents (e.g., viral hemorrhagic fever viruses, SARS, MERS CoV, and others), there is no available vaccine. Others have a vaccine, but it is only available to laboratory workers (i.e., tularemia), not approved by the U.S. Food and Drug Administration (FDA) for PEP use (i.e., anthrax), or not feasible for use as PEP because it takes months to develop immunity (i.e., botulism). Vaccination during a pandemic may be possible, but will likely be delayed. It could take weeks to months to identify the causative strain and develop an effective vaccine against it. Even after the strain is identified, it may take months to ramp up vaccine production to create enough vaccine for the entire United States or world. As of fall 2013, there were multiple FDA-approved vaccines against the current circulating strain of avian influenza A (H5N1).[55]Other vaccines against H5N1 avian influenza and other strains of influenza (H7N9 and H3N2 to name just two) are also under development. These vaccines may provide limited protection during a pandemic but would likely not be completely effective. This is because the current H5N1 avian influenza vaccines are effective against the current circulating strain. However, the influenza strain must mutate to become more easily transmissible from person to person and thus able to cause a pandemic. This mutation may render the current avian influenza vaccine less effective or ineffective. It is anticipated that vaccine distribution during a pandemic may be delayed by 9 months or more because of the time needed to develop and produce a new vaccine.[12]

In the event of a large-scale infectious disease disaster, mass distribution of medical countermeasures may be required in the form of antimicrobial therapy/prophylaxis distribution or vaccination administration. Mass distribution of medical countermeasures requires extensive upfront planning to accommodate large numbers of exposed individuals in a short period of time. Mass distribution is generally accomplished through PODs. There are two types of PODs: open and closed. Open PODs are distribution sites that dispense medical countermeasures to all community members; these sites are coordinated by local public health officials. Closed PODs are distribution sites that are located within a workplace or other private employer setting and only dispense medical countermeasures to employees and/or employees' family members. Open POD development and implementation is a multiagency endeavor, as it will need to be a communitywide effort. Healthcare agencies should consider becoming closed PODs, so as to be able to quickly distribute medical countermeasures to their own employees, patients, visitors, and volunteers. This may ensure faster service and enable healthcare employees to continue working throughout the infectious disease disaster. If healthcare facilities or agencies want to be a closed POD site, they should work with public health officials prior to an event, as formal arrangements need to be in place in order for an agency to become a closed POD.

During an infectious disease disaster, medical countermeasures may be limited. The CDC's SNS is a national repository of medications and supplies needed for a disaster. The SNS is intended as a

supplement for situations in which local resources are exceeded by need. Medications and supplies in the SNS are located throughout the United States and can be delivered to any state within 12 hours. Healthcare facilities/agencies and communities need to remember that the SNS is supplemental only. In the event of a large-scale infectious disease disaster, especially a pandemic, the current SNS supplies will not be sufficient to cover all communities. The United States experienced this during the 2009 H1N1 pandemic when many hospitals reported running out of N95 respirators early on in the pandemic, and the supplies they received from the SNS were inadequate in number or size/type.[21]Healthcare facilities/agencies and communities need to be as proactive as possible in preparing for infectious disease disasters to ensure the best response. One way to do this is to stockpile or make arrangements to obtain additional supplies during a disaster. Although this is widely regarded as an essential component of emergency management, a recent study of U.S. hospitals found that only 63 percent of hospitals are stockpiling or have arrangements to obtain additional medications (e.g., antibiotics, antivirals) during an infectious disease disaster.[3]Healthcare facilities and communities need to prioritize who will receive limited supplies. This should be done as part of emergency management planning and not wait until supplies are insufficient or depleted. Guidance on allocating scarce resources ethically can be obtained from the Institute of Medicine.[56]

Anti-infective Therapy, Prophylaxis, and Vaccination for Elderly and Immunocompromised Individuals

Anti-infective therapy, chemoprophylaxis, and vaccination will be the same for the elderly and immunocompromised as it is for healthy adults for most diseases, but there may be more adverse effects in the elderly and immunocompromised. The elderly will be at high risk from drug-to-drug interactions and adverse events from anti-infective therapy and chemoprophylaxis during an infectious disease disaster because of their likelihood of having comorbidities.[49]Immunocompromised individuals are at increased risk from adverse events related to administration of live vaccines, such as the smallpox vaccine.

Anti-infective Therapy, Prophylaxis, and Vaccination for Pediatrics

Anti-infective therapy for children will differ from adults for most diseases. These differences range from smaller doses that are based on weight to elimination of certain medications because of adverse effects in children (e.g., teeth stain due to tetracycline in children younger than 8 years).[57]One example is that infants younger than 6 months may not be vaccinated against influenza, which would put them at risk from infection during an influenza pandemic.[43]However, infants may receive some passive immunity protection up to 6 months after birth from the mother's vaccination during pregnancy. There are identified therapies and pediatric-specific doses for most bioterrorism-related bacterial infections; antiviral therapy for pandemic influenza, SARS, and other viral illnesses; antitoxin for botulism; and vaccines for some diseases that could cause an infectious disease disaster.[57]However, there are not a lot of data available on the efficacy and safety of these medical therapies in children; further research is needed in this area.

INFECTION PREVENTION PROCEDURES

The amount of IP involvement in disaster response depends on the agent involved. In an infectious disease disaster, IP involvement will be critical, especially if the agent is communicable. Many agents of bioterrorism are not transmitted from person to person, but some are. Most emerging infectious diseases are communicable, but a few are not. Bioterrorism agents and emerging infectious diseases

that are communicable pose the greatest risk to society and will require the most involvement from an IP. Examples of potential infectious disease disasters that involve communicable diseases include pneumonic plague, smallpox, viral hemorrhagic fever viruses, SARS CoV, MERS CoV, and pandemic influenza. In these instances, infection prevention will be essential to control the outbreak, prevent future cases, and decrease morbidity and mortality associated with the event.

Isolation and Personal Protective Equipment Use

In addition to pharmacological interventions (anti-infective therapy, chemoprophylaxis, and vaccination), nonpharmacological interventions should be implemented to prevent and control disease spread during an infectious disease disaster. The primary nonpharmacological intervention involves isolation and PPE use. Standard Precautions should always be used when caring for patients, patient care equipment, and environmental controls. Respiratory etiquette (also known as respiratory or cough hygiene) should be implemented as part of routine infection prevention activities, but are especially important during infectious disease disasters. Information on Standard Precautions, isolation, and respiratory etiquette are outlined in **29. Isolation Precautions (Transmission-based Precautions)**. These simple measures are very important during an infectious disease disaster, but research indicates that many healthcare personnel do not follow them correctly during biological events. An epidemiological study found that 40 percent of healthcare personnel who developed SARS after exposures to coughing patients had not been wearing a mask when exposed; many, if not all of these infections may have been prevented if the healthcare personnel had been wearing respiratory protection.[58]A study conducted in New York City during the 2009 H1N1 pandemic examined unprotected staff exposures to H1N1 patients and found that there were 277 unprotected staff exposures from 26 H1N1 patients, 65 percent (179) of which were preventable if staff had correctly followed Transmission-based Isolation Precautions.[59]Hand hygiene is also an important component of respiratory etiquette and response to an infectious disease disaster. See **27. Hand Hygiene**, for more information. The final component of respiratory hygiene is spatial separation. Spatial separation for infectious disease disasters involves physically separating potentially contagious patients from noncontagious people. Approximately 3 feet is needed to prevent the spread of respiratory diseases, including those involved in infectious disease disasters, such as SARS and pneumonic plague.

The exact necessary infection prevention procedures needed for a bioterrorism attack cannot be estimated before an attack occurs. It depends on many factors, including (1) how soon the release is detected (i.e., whether decontamination and prophylaxis are necessary), (2) how soon the diagnosis is made, (3) how soon appropriate isolation was initiated (i.e., the number of potential contacts of an infected case), (4) the size of the release (i.e., the number of affected individuals), and (5) the agent used (i.e., whether the agent is contagious). However, the basic principles of infection prevention still apply. Infection prevention principles and recommendations are not altered for bioterrorism; they are the same whether the event is intentionally inflicted (bioterrorism) or a naturally occurring incident (emerging infectious disease outbreak or pandemic).

Any time a bioterrorism-related or emerging infectious disease is suspected, infection prevention guidelines for that specific agent/disease should be followed. During the beginning of an infectious disease disaster when the agent may not have been identified or when there is not enough evidence regarding the disease transmission route, IPs need to base infection prevention decisions on syndromes and symptomatology. This is referred to as syndrome-based isolation/control measures. This will be especially important during an infectious disease disaster involving a newly emerging infection because there may be limited or no information available on the causative agent. MERS CoV was an example of this situation. When MERS CoV first emerged in 2012, the transmission route and control measures

needed to prevent disease spread were unknown. Infection prevention decisions were made on the basis of patients' symptoms, epidemiological information as it became available, and basic infection prevention principles.

Some general guidelines to follow when the causative agent is unknown include the following: (1) if the patient has respiratory-type symptoms (e.g., cough, sneezing, fever), Droplet Isolation Precautions should be used; (2) if the patient is severely ill with rapidly progressing respiratory symptoms and an airborne spread disease is suspected (i.e., SARS or avian influenza), Airborne Precautions should be considered; (3) if the patient has GI symptoms (e.g., nausea, vomiting, diarrhea), Contact Precautions should be used; (4) if the patient has an unusual rash (especially if it is centrifugal in pattern), smallpox should be considered and Contact and Airborne Isolation Precautions should be used; (5) if the patient is bleeding profusely from multiple orifices for no logical reason (i.e., no history of recent trauma, surgery), viral hemorrhagic fever should be considered and Contact and Airborne Isolation Precautions should be used; (6) if the patient has any type of unusual or severe lesion or wound for no logical reason (i.e., no recent history of surgery, injury), Contact Precautions should be implemented; (7) if the patient has an enlarged and very painful lymph node, bubonic plague should be suspected and Contact Precautions should be used if the skin is broken or there is draining fluid; and (8) if the patient has descending flaccid paralysis and botulism is suspected, no isolation is necessary. Table 120-5 provides an outline of syndrome-based isolation precautions that can be used during an infectious disease disaster until the causative agent is identified and/or event-specific isolation guidelines are provided by the CDC. PPE use should follow standard healthcare facility procedures, including recommendations provided as part of respiratory hygiene/cough etiquette. In the event of an outbreak of an emerging infectious disease in which the causative agent is not known, healthcare personnel should be told to follow official recommendations from their infection prevention/hospital epidemiology department, their local public health authorities, or the CDC. Healthcare personnel should be encouraged to wear PPE that is appropriate to the situation and the task that they are performing.

Table 120-5 Syndrome-Based Isolation Categories/Control Measures for Infectious Disease Disasters in Which the Causative Agent is Unknown

Symptoms/Syndrome	Isolation Precaution Category*†
Respiratory	
Cough, runny nose, watery eyes	Droplet
Fever (>101.1°F) and cough in adults**	Droplet
Fever (>101.1°F) and cough in children	Droplet and Contact
Fever (>101.1°F), cough with bloody sputum, and weight loss or with upper lobe pulmonary infiltrate in an HIV-negative patient or any lobe of an HIV-positive patient	Airborne and Contact, plus eye protection when performing aerosol-generating procedure
Fever (>101.1°F), cough, and pulmonary infiltrate in any lobe in patient with a travel history to country with active cases of SARS or avian influenza within past 10 to 21 days**	Airborne and Contact, plus eye protection
Diarrhea or vomiting	
Vomiting	Standard
Acute diarrhea with a likely infectious cause in an incontinent or diapered patient	Contact

Watery or explosive stools, with or without blood	Contact
Skin	
Fever (>101.1°F) and rash	Airborne
Fever (>101.1°F), upper chest rash, and stiff/sore neck	Droplet
Eye infections (drainage from eye)	Standard
Draining wound/lesion that cannot be covered	Contact
Rash	
—Itchy rash without fever	Contact
—Petechial/ecchymotic with fever	Droplet for 24 hours of antimicrobial therapy
—Rash and positive history of travel to an area with a current outbreak of very high frequency in the 10 days before fever onset	Droplet and Contact, plus eye protection (goggles or face shield). Add N95 or equivalent when performing aerosol-generating procedures
—Maculopapular with cough, coryza, and fever	Airborne
—Vesicular, especially if centrifugal in pattern	Airborne and Contact

*Always use Standard Precautions.

†If the causative agent is known, the appropriate isolation precautions for that disease should be used.

A temperature of 100°F should be used as the identifier for potential infection to identify the elderly or immunocompromised individuals whose physiological changes tend to mask normal signs of infection.49**In addition, clinical judgment should always be used.

Adapted from Rebmann et al.**61**and Siegel et al.**64**

During routine activities, isolation is generally only implemented in hospitals. However, during an infectious disease disaster in which hospitals will be full and potentially contagious patients may be triaged to alternate care sites or home health, communities should consider educating the public regarding how to implement basic infection prevention strategies in nonhospital settings. This may include isolation and PPE use in long-term care, alternate care sites, home health, medical clinics, community-based evacuation shelters, and any other site that administers healthcare services or houses potentially contagious patients.[60]Home isolation may also be recommended for individuals who are ill and contagious but do not require inpatient treatment.

PPE and other medical supplies are expected to be insufficient or depleted during an infectious disease disaster. Guidelines for stockpiling PPE for biological events have been proposed,[61]and are summarized in Table 120-6. If supplies of respirators become insufficient during disasters, despite local and regional stockpiling efforts, healthcare agencies should implement crisis standards of care related to extending the use or reuse of respirators. Guidance for developing a respirator crisis standard-of-care policy should be based on existing guidelines.[62]See **119. Emergency Management**, for more information on how to manage a shortage of PPE and other medical equipment.

Table 120-6 Estimated Numbers of Postexposure Prophylaxis Needed for an Infectious Disease Disaster*

Category of Staff	Respirator	Gown (disposable)	Gloves (disposable)	Goggles/Eye Protection
Little to no exposure	1 disposable per contact/exposure	1 per exposure	1 pair per contact	None
Prolonged exposure	1 reusableper outbreak (plus 2 cartridges/month**)	1 per exposure	1 pair per contact	1 per outbreak
Infrequent exposure(s)	1 reusableper outbreak (plus 2 cartridges/month**)	1 per shift	1 pair per contact	1 per outbreak

Estimates are based on staff's expected exposure risk during the event.

*Adapted from: Radonovich LJ, Magalian PD, Hollingsworth MK, et al. Stockpiling supplies for the next influenza pandemic. *Emerg Infect Dis*2009;15(6):e1.

**Disposable respiratory cartridges are needed for reusable respirators.

Social distancing practices may also be implemented during an infectious disease disaster as a nonpharmacological intervention. Social distancing refers to a set of practices that aim to reduce disease transmission through physical separation of individuals in community settings. These practices have been outlined in DHHS' document *Community Strategy for Pandemic Influenza Mitigation*.[63]

Examples of social distancing include (1) home quarantine (staying at home after exposure to a potentially contagious person); (2) closing schools and childcare programs; (3) keeping children and teenagers out of public places, such as malls, movie theaters, and other common gathering areas; (4) canceling large public gatherings of any kind; (5) encouraging people to work from home when their jobs allow or adjusting schedules to decrease the number of workers in the same place at the same time; (6) arranging for community-based medical services that keep noncontagious individuals away from potentially contagious people (e.g., setting up prenatal classes in community sites rather than at hospitals, encouraging home birth); and (7) implementing other interventions that decrease interaction between individuals in communities as a way of decreasing the risk of disease transmission.[52,63]

Quarantine

Quarantine is the separation of individuals who are not yet symptomatic but have been exposed to a contagious person and are believed to be at risk of developing an infection. These exposed individuals are quarantined or separated from others as a way to rapidly identify onset of illness if it occurs and keep them away from susceptible people. Once a person in quarantine develops signs or symptoms of disease, it would be assumed that they are infected and they would need to be isolated. Quarantine also implies exclusion of healthy individuals from areas that are known or suspected of being contaminated or housing infected patients. Time periods for quarantine depend on the disease to which the person was exposed. Generally, the quarantine time is equal to the length of the incubation period for the disease to which the person was exposed. Quarantines can be voluntary or enforced.

Quarantine is only to be considered in drastic circumstances, such as the emergence of a new highly pathogenic infectious disease or the use of smallpox as a biological weapon. Quarantine can be implemented in a variety of places, including community settings (e.g., a hotel or convention center), the home, or even in hospitals (i.e., work quarantine).[43] Interventions used as part of home and work quarantine are outlined in Table 120-7. Monitoring (either self-monitoring or external) must be in place for all quarantined individuals, regardless of where they are quarantined, to identify rapidly potentially infected or contagious individuals and institute appropriate therapy. It is generally recommended that quarantined individuals be housed in separate rooms; however, a study conducted in China during the 2009 H1N1 pandemic found that there was no increased risk of infection for quarantined students housed two to a room compared to those in single-person rooms.[64] Therefore, double-occupancy quarantine housing may be considered if space is limited.

Table 120-7 Interventions for Implementing Home or Work Quarantine as Used during the Severe Acute Respiratory Syndrome Outbreak

Home Quarantine
Individual is instructed to: —Wear mask when in contact with household members. —Monitor and record temperature twice daily. —Report any elevated temperature or other symptoms to public health. —Stay physically separated from others in the home whenever possible, including having a separate sleeping area/room and bathroom when feasible. —Keep separate linens (towels, sheets, pillowcases) and eating utensils (i.e., dishes, silverware) that are not shared with other household members. —Do not have visitors. —Do not go to any public gatherings or community activities, including shopping. —Stay in the house at all times. If the individual must leave the house (e.g., to get the mail), he/she should take a mask to put on if someone comes into the yard. —Walk dogs or other pets in the backyard only.
Work Quarantine (used after an individual had been exposed to illness during an occupational exposure)

Individual is instructed to: —Work at only the healthcare facility at which the worker was exposed, and then only if symptoms are not present. —See only essential patients in community-based clinics (if the healthcare personnel has a community practice in addition to hospital duties) and refer nonessential patients to other medical facilities. Wear a mask and have office staff wear a mask at all times. —Monitor and record temperature and symptoms before beginning work; elevated temperatures or other symptoms should be reported to the health department. —Drive to work alone in a private vehicle (i.e., do not use public transportation). —Wear mask at all times when at work. —Adhere to hand hygiene practices meticulously. —Eat in a room that is physically separated from others if possible; if not feasible, individual should stay at least 6 feet away from others. —Do not go to other medical centers, clinics, or hospitals unless authorized by the health department before visit. —When not at work, the individual must follow home quarantine guidelines.
Adapted from Reynolds et al.[67]

Home quarantine can be considered a means of social distancing and it was used as one such intervention in Canada during the SARS outbreak,[65] and in China,[66] Australia,[67] and Japan[68] during the 2009 H1N1 pandemic. A study conducted in Japan during the 2009 H1N1 pandemic aimed to assess the effectiveness of voluntary home quarantine among car production company personnel. This study found that voluntary home quarantine with paid time off was effective at lowering the overall incidence of infection among workers (reduced risk of infection by 20 percent); however, those who stayed home and obeyed the quarantine were two times more likely to get infected themselves compared to those who went to work.[68] This is believed to be because the workers who followed the quarantine probably had more close contact with their sick family member while they were at home. Another study conducted during the H1N1 pandemic had different findings; that study found that home quarantine may have been effective at decreasing the transmission rate early on during the pandemic, but it became significantly less effective as the rate of community transmission increased.[66]

Home quarantine should be considered if a young child requires quarantine so that the child can stay with the parent/primary caregiver. Multiple studies have found that U.S. citizens strongly prefer home quarantine over quarantine in a separate facility.[69,70] In contrast, research indicates that citizens from Hong Kong, Singapore, and Taiwan (who had experienced home quarantine during the SARS outbreak or had known individuals who had) reported that they strongly prefer quarantine in a separate facility.[70] The reasons for this difference are not known, but it is believed to be associated with the reality of home quarantine (i.e., fear of infecting household members, protective measures that needed to be implemented in the home, such as wearing a mask when around others, not sleeping in the same room). Research also indicates that U.S. citizens are more willing to comply with quarantine when it is voluntary versus when the government requests or orders it.[69]

Individuals in home quarantine may develop signs of infection and become too ill to stay at home, which would require transfer to a healthcare facility. Communication must be provided to quarantined individuals regarding: (1) why they are being quarantined, (2) how long their quarantine will last, (3)

protective measures they must take while being quarantined, (4) how to monitor themselves for illness or how they will be monitored, (5) symptoms that need to be reported, (6) to whom they report symptoms or changes in health status, (7) how psychological support will be provided, (8) how compliance will be monitored, and (9) consequences for noncompliance.

Work quarantine was implemented during the SARS outbreak in Canada; results regarding its effectiveness as a means of controlling disease spread are conflicting.[71,72] In addition, hospital/work quarantines implemented during the SARS outbreak were found to be expensive and had a negative psychological effect on healthcare personnel.[65] Future use of work quarantine as a nonpharmacological intervention needs to be evaluated. If a hospital-based work quarantine is to be implemented, provisions must be made to provide sleeping arrangements, food, water, and other essential services to those quarantined.

Regardless of the setting used for quarantine, one major potential obstacle to quarantine effectiveness is a lack of compliance. Research from the SARS outbreak indicates that only about half of all quarantined individuals were compliant with all community protective measures while on home quarantine;[65] these measures included such things as not going out of the house to socialize, not attending public events, not going on vacation, not running errands, and not allowing visitors into the home. Compliance with household protective measures was even lower: Only 38.4 percent complied with household protective measures, such as using separate towels and utensils, sleeping in a separate room, and using a mask when around others in the home.[65] A study conducted in Australia during the 2009 H1N1 pandemic had similar findings; compliance with home quarantine was only 53 percent.[67] A 2010 study[69] found that those who have a higher perceived susceptibility to avian influenza are more likely to report willingness to comply with home quarantine; education campaigns could be used to increase home quarantine compliance by focusing on the risk of disease development.

When considering the implementation of quarantine, one factor that needs to be considered is the potential for psychological stress associated with being quarantined. Two studies conducted with individuals who had been quarantined during the 2003 SARS outbreak found that quarantine causes a lot of psychological stress.[65,73] Quarantined individuals report feeling frightened, lonely, bored, frustrated, angry, and fearful of becoming infected, infecting their family or friends, and losing income while being quarantined.[65,73] Research indicates that there was also a certain level of stigma associated with being quarantined during the SARS outbreak, and this contributed to psychological distress among the quarantined.[65] However, the same level of psychological distress associated with quarantine was not found during the 2009 H1N1 pandemic. A study conducted with college students who had been quarantined for 7 to 10 days found that there were no negative psychological consequences from the quarantine.[74] The researchers postulated that the higher psychological impact during the SARS outbreak may have been related to the high mortality rate seen during the SARS outbreak, which could have caused more stress among those who were quarantined compared to those who were quarantined during the H1N1 flu pandemic that had a much lower mortality rate (10 percent mortality during the SARS outbreak versus <1 percent during the H1N1 pandemic).[74] If this is true, then a future event that involves an infectious disease with a fairly high mortality rate would be expected to result in higher rates of negative psychological stress while individuals are quarantined, and this should be factored into the decision-making process and/or addressed in mental health interventions among the quarantined.

Discussions regarding quarantine policies and procedures should include all of the following groups: (1) local law enforcement, (2) public health agencies, (3) facility administration, (4) security, (5) facility law representatives, (6) infection prevention, and (7) hospital epidemiologist or infectious disease physician/department. Other groups may need to be included, depending on the community and the agency/group that intends to implement quarantine. Current quarantine policies and procedures for healthcare facilities or agencies should be evaluated. In addition, healthcare facilities should partner with local public health officials to evaluate and update existing quarantine laws as needed.

Food Safety

For most infectious disease disasters, food safety will not be a primary concern. Pandemics, for example, will not pose a huge risk of foodborne illness, unless staffing shortages lead to poor food handling or inadequate environmental decontamination in food service industries. However, food safety will be critical if the infectious disease disaster involves a foodborne illness outbreak. Examples might include a bioterrorism attack using a foodborne illness agent, such as botulism, *Salmonella*, or *Shigella*, an agroterrorism attack that involves the infection of livestock or poultry, or if the event involves an emerging infectious disease that is linked to food sources, such as livestock.

An important aspect of biosecurity is ensuring that military and civilian food sources do not become compromised. This is one reason why veterinarians have started collaborating with public health officials to conduct surveillance of livestock: to monitor for potential bioterrorism attacks or emerging infectious zoonotic diseases. If food supplies do become compromised or contaminated, an investigation would need to be conducted. One possible intervention would include conducting environmental sampling; samples would be needed from the food involved, the processing or rendering plant or factory where the animals or food was processed, food preparation areas (if it's a restaurant), and utensils or other equipment that may be involved in the outbreak. Any facility that might be involved in the outbreak may need to be closed down temporarily. Examples include restaurants, rendering plants, dairy or animal farms, or food processing factories. Food safety education and training will be essential during foodborne outbreaks to ensure that workers understand how to safely handle food and decontaminate food preparation areas and equipment.

Water Safety

Water safety will not pose a major challenge for most infectious disease disasters. However, if terrorists were able to infiltrate and contaminate military or civilian water supplies, then water safety would be critical. In the past, military forces have deliberately contaminated wells and reservoirs as a means of poisoning civilians.[2,75] In addition, in the 1970s, two terrorist groups attempted to use biological weapons to poison water supplies.[2] Intentional contamination of a municipal water system could lead to serious medical, public health, and economic consequences. Early recognition, timely outbreak investigations, accurate diagnosis, and rapid reporting by the medical and public health community of suspected waterborne terrorism disease cases will be essential to maintaining water security and safety.

An important aspect of biosecurity is ensuring that military and civilian sources of drinking water do not become compromised. Researchers have identified multiple ways in which our water systems could become contaminated during a bioterrorism attack, including before, during, or after water treatment at water treatment plants.[75] Some have argued that contaminating water before or at the water treatment plant would be ineffective because our current water treatment mechanisms would eliminate any infectious disease risk. However, water could easily be contaminated after it leaves water treatment

facilities, such as at water bottling facilities, water supply connections at buildings or in communities, or deliberate contamination of recreational water, such as swimming pools.[75]

If water supplies do become contaminated, an investigation would need to be conducted. One possible intervention would include conducting environmental sampling; samples would be needed from the area or building known to be involved, plus moving backward through the water supply chain to determine the point at which the water first became contaminated. Sampling would identify if the water was only contaminated in a single facility/building or if it became contaminated at a water bottling factory that supplies drinking water to the facility/agency. Waterborne outbreaks can be very challenging to investigate because both animals and humans need water to survive, and animals and humans can get sick from waterborne diseases and then spread them animal to animal, animal to human, or human to human. It might be very complicated to determine that a bioterrorism attack was actually an attack on a water source, if the event involves sick animals and humans. It might look like an aerosol attack on animals, or a foodborne attack on animals that then spread to humans. Any facility that might be involved in a waterborne illness outbreak may need to be closed down temporarily, including healthcare facilities. Public health officials should be notified immediately if waterborne illness is suspected within a healthcare agency.

Healthcare Personnel Surge Capacity

Agencies, organizations, and businesses, including healthcare, should expect high absenteeism rates during an infectious disease disaster. Absenteeism is expected to be higher during an infectious disease disaster than other types of mass casualty events. Up to 20 percent of the workforce may be affected by illness at the same time during a pandemic, and others will be unable or unwilling to work due to family obligations or fear.[12]WHO recommends that emergency managers plan for a 40 percent absenteeism rate during the peak of a pandemic.[12]Healthcare personnel are expected to be infected at the same rate as the general population during an infectious disease disaster, which will further reduce healthcare facilities' and agencies' abilities to respond to such an event.[76]Healthcare facilities and agencies, including long-term care, home health, and community-based medical clinics, need to plan for this increase in healthcare personnel absenteeism. Some recommended ways for increasing healthcare personnel surge capacity include (1) having back-up contracts for obtaining extra staff; (2) providing incentives to get and keep staff; (3) prioritizing healthcare personnel for anti-infective therapy, prophylaxis, and vaccination; (4) offering anti-infective therapy, prophylaxis, and vaccination to healthcare personnel family members; (5) cohorting patients to decrease staff workload; (6) cohorting staff (dedicating healthcare personnel to provide care for potentially contagious individuals and restrict these staff from working with noninfectious individuals); and (7) cross-training staff to provide patient care outside their routine area/specialty to allow for staff resource distribution. One example of effectively using cross-trained staff to help with patient surge during an infectious disease disaster was the Children's Hospital of Philadelphia's use of nonboard-certified pediatric emergency medicine physicians and medical unit nurses in an emergency department during the 2009 H1N1 pandemic; this increased the emergency department's surge capacity when it was most needed.[77]

A variety of incentives should be considered to encourage employees to work during an infectious disease disaster. Examples include monetary bonuses, transportation, housing and subsistence, child/adult family member care, and pet care.[3]Many of the available interventions for increasing worker surge capacity are not currently being implemented in U.S. hospitals. For example, a recent study of U.S. hospitals found that less than a quarter have cross-trained their employees, less than 40 percent have plans to cohort staff, and less than half currently offer incentives to encourage staff to work during

an infectious disease disaster.[3] Of U.S. hospitals that do offer incentives, the three most common incentives offered are free child or adult family member care, temporary housing and subsistence, and healthcare personnel prioritization for anti-infective therapy, prophylaxis, and vaccination.[3] There is no evidence regarding the status of healthcare personnel surge capacity during infectious disease disasters for long-term care, medical clinics, or home health, although it is assumed that surge capacity is no better for these healthcare agencies/groups than for hospitals.

One important incentive to provide healthcare personnel to encourage them to work during infectious disease disasters is to provide them safety measures. This includes prioritizing healthcare personnel for pharmaceutical interventions, such as vaccine and pre- and postexposure prophylaxis, when they are available. Research indicates that providing pharmaceutical interventions to healthcare and public health professionals and their family members significantly increases providers' willingness to work during infectious disease disasters.[78] Despite this, although approximately 80 percent of U.S. hospitals prioritize healthcare personnel to receive anti-infective therapy, prophylaxis, and vaccination during an infectious disease disaster, less than half include healthcare personnel family members in the prioritization plan for pharmacological benefits.[3]

Research indicates that providing adequate supplies of PPE for providers so they can reduce their risk of occupational exposure to infectious diseases also increases the likelihood of healthcare professionals' being willing to work during a biological event.[78] Having adequate supplies of hygiene products and negative pressure rooms for infected patients will also help in limiting the risk of exposure to healthcare personnel and maximize the chances that they will be willing and able to work during a biological event. These issues need to be addressed in healthcare facility disaster planning for infectious disease disasters, so that healthcare personnel surge capacity can be maximized.

There is a caveat to encouraging healthcare personnel to work during an infectious disease disaster: It is imperative that healthcare agencies use a liberal sick leave policy during biological events. Sick healthcare personnel can contribute to the spread of disease during infectious disease disasters, as was seen during the SARS outbreak in which one staff member who worked a single shift while ill was linked to 137 cases of SARS, 45 of whom were other healthcare personnel.[43] Sick healthcare personnel should be furloughed until they are no longer contagious, and the policy should not be punitive.

Decontamination

Decontamination may or may not be an issue after an infectious disease disaster, depending on the following factors: (1) type of event (bioterrorism vs. emerging infectious disease outbreak or pandemic), (2) causative agent, (3) how soon the event is identified, and (4) source of concern (environment or patient). Most infectious disease disasters, including bioterrorism attacks, will likely not require patient or animal decontamination. Pandemics and outbreaks of emerging infectious diseases will not require patient or animal decontamination. In the event of a covert release of a biological agent, patients will not become symptomatic and present to healthcare institutions until days to weeks after the exposure; in this instance, they will most likely have bathed and changed their clothes, thus decontaminating themselves. Only in the event of an announced bioterrorism attack (within 12 to 24 hours after the release) will exposed individuals need to be decontaminated. Patient decontamination consists of bathing, including shampooing of hair, with plain soap and water, and changing their clothing.

Given existing knowledge, environmental decontamination is not considered necessary for outside sources, such as streets, cars, or the outside of buildings after a bioterrorism attack. This is because

weather plays a key role in rapidly disseminating biological agents in outside air.

Indoor environmental sources may require extensive decontamination strategies after an infectious disease disaster, but the interventions vary according to the agent involved and the nature of the event. For example, more stringent decontamination methods are necessary for a bioterrorism attack using anthrax (because of the hardy nature of spores). As the 2001 bioterrorism attacks illustrated, equipment or areas may require specialized decontamination strategies, such as contained buildings, ventilation systems, or machinery with small parts. The costs of decontamination following the 2001 anthrax bioterrorism attack are estimated at $320 million.[4]

Other agents, such as smallpox, require diligent environmental decontamination as well. Smallpox can be spread through direct hand-to-hand contact or indirect contact with fomites, making decontamination of environmental surfaces imperative to prevent secondary transmission. Only EPA-registered, healthcare facility-approved germicides are required for environmental decontamination of smallpox, although a 0.5 percent hypochlorite solution may be used (this solution is made by mixing one part household bleach with nine parts water). In the event of a single smallpox case, scrupulous attention to contact precautions, including good housekeeping with EPA-approved germicides, would be critical to prevent secondary spread. Other potential bioterrorism agents and emerging infections that can be spread by hand-to-hand contact, such as viral hemorrhagic fevers and SARS, would require stringent environmental decontamination as well. Additional information on decontamination can be found in **119. Emergency Management**.

Animal Control

Animal control may be an important nonpharmacological intervention during an infectious disease disaster, depending on the event. Contact with animals, both domesticated and nondomesticated, can lead to the spread of zoonotic illness. Management of service animals for disabled individuals or those that are used for healthcare-related procedures are covered in **122. Animals Visiting in Healthcare Facilities**.

Management of animals is less likely to be needed during an infectious disease disaster compared to a natural disaster that results in the displacement of individuals from their homes, but animal control may be essential during biological events that involve an animal vector, such as a West Nile virus, swine flu, or avian flu outbreak. Animal control interventions necessary for infectious disease disasters will primarily be a public health concern. Examples include surveillance of swine and poultry during avian or swine influenza pandemics, education of employees at meat rendering plants or poultry farms, and education of the general public about safe handling of animals while hunting. Animal control should not be an issue for healthcare agencies during infectious disease disasters, unless the animals are vermin.

Pest Control

Natural disasters, especially hurricanes and floods, are likely to result in an increase in insects and other pests in or around the affected community due to rain and high water levels. Healthcare facilities may become infested with insects and/or vermin seeking warmth, moisture, and food. This is less of a concern for infectious disease disasters because there most likely will not be a significant environmental disruption that will cause pests to seek out medical facilities. However, if the biological event involves a vectorborne disease, then pest control will be vital. An example would be a bioterrorism attack involving the release of fleas carrying *Yersinia pestis*, the bacteria that causes plague. If carrier fleas were released, they could easily move throughout the community on animals, such as rats, cats, or dogs, and lead to human illness. If such an event occurs, vector control interventions will be vital to stop the outbreak.

The pest control interventions needed will depend on the disease involved. In the example of a bioterrorism attack involving the release of fleas carrying *Yersinia pestis*, pest control might involve spraying the facility for fleas, or trapping and killing rats if the plague-carrying fleas get into the rat population and rats invade medical facilities. Other pest control interventions would be needed if the vector was mosquitos. Mosquito control measures would include spraying the community for mosquitos, eliminating sources of standing water, and educating the public about mosquito prevention, such as using DEET and wearing long sleeves and pants.

Pest control services should be obtained as needed during an infectious disease disaster, including spraying for mosquitos or setting traps for mice. In addition, the facility's physical structure should be evaluated for any possible entrances for pests, and if found, should be eliminated. Examples include windows with torn or missing screens, unclosed doors that lead to the outside of the building, or sources of standing water.

Postmortem Care

There is a pervasive fear about potential infectious disease outbreaks caused by exposure to disaster victims' dead bodies. However, epidemiological data indicate that there is very little risk of an epidemic related to managing the dead bodies of disaster victims—even infectious disease disasters.[79]However, some infectious disease disasters do pose a threat of disease spread from managing the dead bodies of disaster victims. Examples include outbreaks of cholera, viral hemorrhagic fevers, or smallpox, any of which could put people at risk from disease from exposure to victims' dead bodies if precautions are not taken.[79]

Most of the risk related to handling the bodies of dead victims would be to medical examiners and those involved in conducting an autopsy, because this is an aerosol-generating procedure that could expose those in the room to infectious particles. All of the CDC category A bioterrorism agents could potentially be transmitted during autopsy; in practice, tularemia, viral hemorrhagic fevers, smallpox, glanders, and Q fever have been transmitted to medical examiners while performing autopsy.[80]Therefore, it is essential that pathology departments, medical examiners, coroners, funeral directors, and morgues be informed when the hospital or community is experiencing an infectious disease disaster. This communication should be done before submission of specimens or delivery of bodies. However, past outbreaks of anthrax and smallpox have been first identified from medical examiner autopsy findings.[80]Therefore, infection prevention is essential for all autopsies and pathology procedures.

All autopsies should be performed using Standard Precautions and following routine departmental practices for infection prevention. Standard Precautions for autopsies includes the use of scrubs, a hair bonnet/cap, impervious gown that covers arms, eye protection (face shield or goggles), shoe covers, double gloves, and respiratory protection.[80]Standard respiratory protection for autopsies consists of an N95 respirator or powered air-purifying respirators (PAPR) because of the aerosols routinely generated during the autopsy procedure (e.g., the use of an oscillating saw).[80]Autopsies should also be performed in a negative pressure room/area.[80]Additional biosafety recommendations for medical examiners and autopsy personnel can be found in "Medical Examiners, Coroners, and Biological Terrorism."[80]

Cremation is recommended for handling the bodies of smallpox and viral hemorrhagic fever victims, but mass cremation or mass burial should not be necessary.[79]

Exercises and Drills

119. Emergency Management, outlines the need to perform exercises/drills to assess emergency management plans and how to conduct such exercises. As part of infectious disease disaster preparedness, it is vital that IPs ensure that emergency management drills regularly include a biological agent scenario. These exercises need to involve healthcare facilities, healthcare agencies (including long-term care and home health), and community response agencies to obtain a true sense of the community's preparedness for this type of event. It is also helpful to involve local businesses and schools to fully assess community preparedness for a biological event. A recent study found that although most U.S. hospitals had participated in a disaster drill involving a biological agent scenario in the previous year, approximately 15 percent had not.[3]Many of the hospitals had included community involvement in the exercise and compiled lessons learned from the exercise, but approximately 35 percent had not communicated emergency management plan changes to staff after the exercise.[3]A study conducted after the 2009 H1N1 pandemic found that less than half of all home health agencies engage in regular disaster drills of any kind.[22]A 2011 study[81]found that only 13.6 percent of U.S. businesses overall and 31.3 percent of healthcare agencies have used an infectious disease scenario in a drill or exercise during the past 2 years. Another study found that only 4 percent of schools have incorporated an infectious disease scenario into a disaster drill in the last 2 years.[82]

Conclusions

After the bioterrorism attack using anthrax-laden letters in the United States in 2001 and the numerous outbreaks of emerging infectious diseases that have occurred, including the 2009 H1N1 pandemic, preparedness for biological events has become a necessity for healthcare, public health, businesses, and schools. The world remains always poised for the next pandemic or large-scale infectious disease outbreak. Infectious disease disaster management encompasses the four principles of emergency management—mitigation, preparedness, response, and recovery—and is a multidepartmental and multiagency endeavor. As experts in the fields of surveillance and epidemiology, IPs play a critical role in hospital/healthcare facility and community preparedness, and are responsible for becoming better prepared to effectively recognize and respond to an infectious disease disaster.

Infectious disease disaster preparedness is an ever-evolving process in which facilities and IPs become better prepared to effectively recognize and respond to a mass casualty event involving a biological agent. This is accomplished through facility assessment, development of a response plan, exercise of the response plan, evaluation of the exercise and the facility's and community's level of preparedness, and incorporation of lessons learned from the evaluation into the plan (i.e., emergency management process).

Future Trends

Many issues related to infectious disease disaster preparedness are still being debated, and response strategies are being continuously planned and updated. A few such issues include (1) status of quarantine laws, (2) reimbursement issues related to adverse events associated with the smallpox vaccine, and (3) plan for mass prophylaxis or vaccination distribution. In addition, new guidelines related to avian influenza, smallpox, and other potential infectious disease disaster agents are being evaluated

and updated. It is critical for IPs to stay abreast of the ever-changing knowledge base related to infectious disease disaster preparedness and the etiological agents of concern.

International Perspective

Infectious disease disaster preparedness is an international concern. With the ease and frequency of international travel, it is conceivable for infectious diseases to have a major global impact. SARS is a good example of this phenomenon. Whether intentionally inflicted or a natural event, an outbreak involving an infectious disease is a global issue of concern. Few countries currently have the resources to respond to an infectious disease disaster involving mass casualties.[83] Many countries are working on infectious disease disaster management strategies, both alone and in conjunction with the United States.

Supplemental Resources

Many resources are available for education and training on infectious disease disasters preparedness and the clinical description of potential infectious disease disaster agents. APIC offers many educational opportunities for infectious disease disaster related education. A few examples include multiple webinars provided through the APIC website: **http://webinars.apic.org/**; the APIC Position Paper, *Extending the Use and/or Reusing Respiratory Protection in Healthcare Settings During Disasters*[62]; and numerous other educational initiatives. Please see the APIC Emergency Preparedness website for additional infectious disease disaster training opportunities: **http://www.apic.org/Professional-Practice/Emergency-Preparedness**.

Other website sources include the following:

Centers for Disease Control and Prevention: **http://www.bt.cdc.gov/**

U.S. Army Medical Department. Available at: **http://www.bt.cdc.gov/**.

Johns Hopkins Center for Biodefense: **http://www.jhsph.edu/news/news-releases/2003/preparedness-tips.html/**0

In addition, many public health departments offer infectious disease disaster educational opportunities; check with your local and state public health department(s) for further information.

Abstract

The use of animals in biomedical research is common practice. Although such occurrences are uncommon, personnel working with research animals can be exposed to pathogenic organisms that are carried by animals or that have been given to animals as part of an experiment. The most significant pathogenic agents are discussed in this chapter, along with methods to reduce risk and minimize exposure.

Key Concepts

• Experimentation on animals is an essential and common component of biomedical research.

• Within the animal research setting, most infection risks have been eliminated through improvement in the health and quality of the animals used.

• Two mechanisms to reduce the risk of infection in animal research are providing training in proper animal research methods and techniques and providing an occupational health program for people working with animals.

• A variety of policies and regulations apply to the use of animals in biomedical research. Some of these specifically address infection risks and employee health and safety.

Background

Experimentation on animals is an essential and common component of biomedical research. Animals are used as models in identifying the cause, treatment, and prevention of human disease.[1]Estimates of the numbers of animals used in research vary; however, mice and rats account for more than 90 percent of the mammals used.[2]The remaining mammalian species utilized include hamsters, guinea pigs, rabbits, cats, dogs, pigs, sheep, and various species of nonhuman primates. In addition to mammals, many species of birds, fish, amphibians, and reptiles are used. This variety in species utilization affects the potential for exposure to naturally occurring pathogens. Individuals coming in contact with laboratory animals include scientists, research technicians, veterinarians, veterinary technicians, laboratory animal technicians, and students. Each individual engages in a variety of activities that increase the risk of infection. The purpose of this chapter is to review the factors that affect exposure to naturally occurring and induced infections in laboratory animals and some of the more significant zoonotic diseases that can be encountered.

Basic Principles

ANIMAL QUALITY AND INFECTION RISKS

Animals used in research may be purpose-bred or acquired from the wild or from animal control facilities and shelters.[3]Purpose-bred animals, such as common laboratory rodents (rats, mice, guinea pigs, hamsters, and gerbils), are bred specifically for use in research. Some species may be rederived by cesarean section or embryo transfer and raised in a disease-free barrier to eliminate, not just control, all naturally occurring pathogens.[4]In the course of eliminating all animal pathogens, most or all human pathogens are also eliminated. Rederivation by cesarean section or embryo transfer is commonly used for rodents, whereas larger species such as dogs and cats are rarely rederived; however, extensive efforts are taken to eliminate naturally occurring pathogens by vaccination and strict isolation. Although animal pathogens are eliminated, some human pathogens may remain because rederivation is not undertaken. That is, although animal pathogens have been eliminated, some organisms that are not pathogenic for the animal but are pathogenic for humans may remain. This is because no attempt to rederive the species has occurred.[3]

Conventional animals are those that have varying and uncontrolled health backgrounds. They are generally healthy, and most have been subjected to measures to control the incidence of disease (e.g., vaccination, treatment of specific diseases). No attempt has been made to eliminate human pathogens.[3]

Wild or feral animals are acquired from their natural habitat. Examples include many nonhuman primates, nontraditional rodent species (voles, squirrels, groundhogs), armadillos, and marsupials (opossum). Wild or feral animals pose the greatest risk to humans because the indigenous microbial flora is unknown. They may harbor known and unknown human pathogens.[3]Currently, some nonhuman primates are produced in domestic colonies, but these are more like conventional animals. Most dogs and cats used in research are purpose-bred, but some are acquired from animal dealers or animal

control facilities and shelters.[5]The latter animals often have been exposed to and are incubating many diseases common to that species. Even if purpose-bred, dogs and cats may still harbor naturally occurring agents that are transmissible to humans.[3]Farm animals (cow, sheep, pig, horse) are most often acquired from local farms and are conventional.[3]

INFECTIONS CAUSED BY NATURALLY OCCURRING PATHOGENS CARRIED BY ANIMALS

Zoonoses are diseases transmitted from animals to humans. Literally hundreds of zoonoses have been reported.[6,7]Zoonotic diseases that occur within biomedical and animal research settings have been reviewed elsewhere.[8,9,10,11,12,13]Considerable progress has been made in eliminating and limiting the occurrence of these diseases, but some continue to pose threats to humans. Within the animal research setting, many of the zoonoses have been eliminated as a risk through improvement in the health and quality of the animals that are used; however, a few agents remain a concern to personnel engaged in animal research.[8,9,13,14]Several disease agents of concern are discussed here.

Conventional and wild animals pose the greatest risk to personnel working in animal research because it generally is not known at the time of acquisition whether a pathogen is present. In addition, prevalence rates of any given pathogen in the population may be low, or the organism may be carried latently or even be undetectable. For these reasons, persons working with these types of animals should assume that the animals are infected with potential pathogens and take appropriate precautions.

Through the use of preventive measures within animal facilities, including hazard containment equipment, personal protective equipment (PPE), work practices, and educational awareness, considerable progress has been made in reducing, if not eliminating, the occurrence of certain zoonotic diseases. Most contemporary laboratory animal species are acquired from quality sources (purpose-bred) that maintain animals under specific-pathogen-free conditions, thereby further reducing the risks of zoonotic pathogen infection and transmission. However, certain known zoonoses remain of concern to animal facility personnel, and emerging zoonotic pathogens also must be considered by individuals engaged in animal research.[8,9,13,14]

PATHOGENS BEING USED IN EXPERIMENTALLY INDUCED INFECTIONS IN ANIMAL MODELS

There are two areas in animal research in which the potential pathogen is known and prevention and treatment can be addressed in advance, namely, infectious disease research and recombinant DNA research (i.e., genetic engineering). In the former, animals serve as hosts for the study of the pathogenesis of infectious disease using known agents that are pathogenic for humans. Animals are inoculated with these pathogens under controlled conditions to permit the study of various facets of the disease process for a better understanding of pathogenesis, treatment, and prevention. In the latter, animals are administered viral agents that have been genetically engineered to be incapable of replication in the host and that contain one or more genes that are to be inserted into the host's cells. This technique allows both insertion of new genes or deletion of specific genes. The animal's genome is thus modified to create new animal models (transgenic animals).

ACTIVITIES PERFORMED BY PERSONNEL ENGAGED IN ANIMAL RESEARCH AND ACTIVITIES THAT INCREASE THE RISK OF INFECTION

Husbandry procedures are performed by support personnel who provide daily care to animals. Common husbandry procedures performed include feeding, watering, removal of soiled bedding containing urine and feces, handling and restraint of animals, and sanitizing and disinfecting cages, equipment, and facilities.[14,15,16]These activities expose the worker to traumatic injury from animal bites and scratches and from handling and operation of equipment.[14,15,16]Chemical injuries from disinfectants and sterilants also may occur.[14,15,16]Animal allergy is a common biologic hazard that is encountered.[14,16,17]Naturally occurring animal disease is another biological hazard. Animals undergoing experimental manipulations may have been given radioactive, chemical, or infectious agents, which may further expose the husbandry staff.[14,15,16]Of these activities, risk of infection is associated with animal bites and scratches, injury from soiled equipment, aerosol and contact exposure to pathogens in animal waste, and naturally occurring disease.[14,15,16]Individuals may be exposed by urine splashing into eyes or mucous membranes.

Biomedical procedures are performed by research personnel conducting scientific experiments using animals. In addition, veterinary medical care staff members perform many of the same procedures in providing adequate veterinary care to laboratory animals. Common procedures performed include handling and restraint of animals; injections; collection of blood, urine, feces, and other bodily fluids; surgery; necropsy; and laboratory (bench) activities, such as pipetting, preparing infectious agents and hazardous compounds, and handling animal tissue and fluids.[14,15,16,18]These activities expose the worker to traumatic injury from animal bites and scratches, needlesticks, lacerations from laboratory glassware and surgical and necropsy instruments, animal allergy, and naturally occurring pathogens.[14,15,16,18]Of these activities, infection risks are associated with animal bites and scratches, lacerations and aerosol exposure to infected tissues during surgery and necropsy, and needlesticks. Animals given radioactive, chemical, or infectious agents may pose further risk to staff.[14,15,16,18]

INFECTION PREVENTION TECHNIQUES THAT REDUCE THE RISK OF INFECTION

One important mechanism for reducing the risk of infection in animal research is providing training in proper animal research methods and techniques. Handling and restraint of animals are nearly unavoidable procedures that must be performed by most individuals engaged in animal research. Proper training of personnel in handling and restraint of animals is essential to reduce injuries from animal bites and scratches.[14,16]An adjunct to proper handling and restraint is the use of anesthetics and tranquilizers to manage wild animals and fractious animals that resist handling.[14,19]It is essential that staff receive proper training in the use of these agents for chemical restraint to ensure that proper dosages are used and that animals are adequately anesthetized or tranquilized to prevent loss of animal life due to overdosage.[19]Anesthetized animals must be monitored for respiratory rate, heart rate, and temperature to maintain an appropriate level of sedation.

Another effective means to reduce the risk of employee infections in the animal research setting is to implement an occupational health program for personnel working with animals. Such programs are required under current standards.[14,15,16,20]The principal concern of such a health program is to protect personnel from and to monitor exposure to hazards emanating from the animals themselves, such as animal infectious agents that are transmissible to humans (zoonoses), animal bites, and allergies to

animals. An effective health program for animal handlers also will take into account secondary hazards associated with working with animals, such as radiation exposure when animals are given radioactive materials during the course of an experiment and exposure to toxic chemicals that may be given to animals as part of an experimental protocol.

Health programs should include an educational program to provide staff members with information about zoonoses, personal hygiene, animal bites, allergies, and precautions to be taken by pregnant women. Under some circumstances, periodic physical examinations may be necessary. In some programs, pre-employment and postemployment serum samples may be banked for reference.[14,15,16,20]

A health program also includes immunization against selected diseases. Minimally, tetanus immunization should be provided. In addition, pre-exposure immunization against rabies and Hepatitis B virus should be considered if personnel will be in contact with animals that may be infected with these agents. If biohazardous agents for which vaccines are available are being used experimentally, consideration should be given to prophylactic immunization.[14,15,16,20]

Employees should receive instruction regarding the occupational hazards associated with animal research.[14,15,16,20]Many healthcare providers are unfamiliar with infectious hazards that may be encountered in the animal research setting; therefore, it is incumbent on the employee to be well informed about possible infectious hazards to assist the physician in identifying possible causes of presenting signs and symptoms and establishing a diagnosis when the employee becomes ill.

Most species of nonhuman primates are susceptible to tuberculosis; therefore, nonhuman primate colonies are routinely screened for this disease. If nonhuman primates are being used, personnel should be screened regularly for tuberculosis.[14,15,16,20]

Employee training should include instruction on the use of protective clothing and personal protective devices.[14,15,16,20]Specifically, laboratory coats or surgical gowns, gloves, surgical masks or respirators, and eye protection should be used. The type of protective clothing and devices required is determined by the risk of infection. For example, all the preceding items would be required when handling nonhuman primates of the genus *Macaca*, but only gloves and a laboratory coat when handling pathogen-free rats or mice. Personnel should wash their hands as often as necessary to maintain personal hygiene. Employees should not eat, drink, or apply cosmetics in animal rooms.

Individuals operating animal facilities should have strict policies regarding visitation. Access to animal housing areas and laboratories should be limited to authorized personnel. With prior arrangement, visits by other employees or the public may be permitted, but entry should be limited to low-risk areas.

Animal Research And Diagnostics

APPLICABLE REGULATIONS AND STANDARDS FROM FEDERAL AGENCIES AND ACCREDITING ORGANIZATIONS

Animal Welfare Act

The Animal Welfare Act was enacted in 1966 and has been amended multiple times.[21]The act was initially intended to prevent theft and sale of pet dogs and cats and to ensure the humane care and

treatment of animals used in research. The latter objective has been expanded greatly through the amendments and currently accounts for the primary focus of the regulations.[22] The act and regulations are administered by the U.S. Department of Agriculture (USDA). Within the USDA, the responsibility rests with the Animal Care program office of the Animal and Plant Health Inspection Service.[22]

The act and regulations mandate standards for the humane handling, care, treatment, and transportation of dogs, cats, guinea pigs, hamsters, rabbits, nonhuman primates, marine mammals, and other regulated warm-blooded animals. At present, rats, mice, birds, horses, and farm animals are not regulated species.[22] The regulations require that each research facility appoint an institutional animal care and use committee (IACUC) to ensure compliance with the act. The IACUC inspects all animal facilities and reviews the institution's animal care and use program at least once every 6 months. The IACUC reviews all research activities involving animals and must approve those activities before the work can be conducted.[22] The regulations also require that each facility establish a program of adequate veterinary care for animals used in research.[22]

Public Health Service Policy on Humane Care and Use of Laboratory Animals

The *Public Health Service (PHS) Policy on Humane Care and Use of Laboratory Animals*[23] was originally published in 1971. It was revised following passage of the Health Research Extension Act of 1985 (Pub Law No. 99–158). That act required the secretary of the Department of Health and Human Services, acting through the Director of the National Institutes of Health (NIH), to establish guidelines for the proper care and treatment of animals used in research, including the appropriate use of tranquilizers, analgesics, anesthetics, paralytics, and euthanasia; appropriate presurgical and postsurgical veterinary medical and nursing care; and the organization and operation of animal-care committees. The policy is intended to implement general government recommendations on animal care and use contained in the federal publication *U.S. Government Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training*.[23] The Office of Laboratory Animal Welfare (OLAW) at the NIH is charged with ensuring compliance with the policy.[23] The policy applies to all PHS-conducted or PHS-supported activities involving animals, regardless of where they are conducted. An animal is defined as any live, vertebrate animal used or intended for use in research, training, or testing.[23]

Each institution must submit a document termed an Animal Welfare Assurance to OLAW. The assurance must describe three components: the institutional animal care and use program, whether the institutional animal care and use program is accredited, and the IACUC. The institutional official must sign the assurance. OLAW evaluates assurances to determine the adequacy of the institution's animal care program. Without an assurance, PHS-supported animal research is not permitted. Assurances are valid for as long as 4 years.[23]

The PHS policy requires each institution to appoint an IACUC, as does the Animal Welfare Act. The functions of the IACUC are as follows:

• Review the program every 6 months for humane care and use of animals using the *Guide for the Care and Use of Laboratory Animals* as the standard.[20]

• Inspect the animal facilities every 6 months using the guide as the standard.

• Prepare reports on findings and submit these to the designated institutional official.

• Review concerns involving animal care and use at the institution.

• Make recommendations to the institutional official regarding any aspect of the animal program, facilities, or training.

• Review and approve, and require modifications in or withhold approval of, proposed or ongoing activities related to the use and care of animals.

• Review and approve, and require modifications in or withhold approval of, proposed significant changes regarding the use of animals in ongoing activities.

• Be authorized to suspend activities involving animals that are not conducted in accordance with the institutional assurance, policy, guide, or Animal Welfare Act.[23]

The IACUC must conduct a review of those components of research projects related to the care and use of animals and determine that the proposed research projects are in accordance with the policy, the Animal Welfare Act, the guide, and the institutional assurance.[23]The review must confirm the following:

• Procedures are conducted to minimize pain, distress, and discomfort to the animals.

• Procedures that may cause more than momentary pain or distress are conducted using appropriate anesthetics, analgesics, and tranquilizers unless the procedure is justified for scientific reasons in writing by the investigator.

• Animals are euthanized if pain or distress cannot be relieved.

• The living conditions of animals will be appropriate for the species and contribute to their health and comfort. The housing, feeding, and nonmedical care of animals will be directed by a veterinarian or other scientist trained and experienced in the proper care, handling, and use of the animal being maintained.

• Medical care must be available and provided as needed by a veterinarian.

• Research personnel must be appropriately qualified and trained to perform the procedures described in the protocol.

• Euthanasia methods must conform to the standards in the *American Veterinary Medical Association Guidelines for the Euthanasia of Animals: 2013 Edition*unless a deviation is justified for scientific reasons in writing by the investigator.[24]

Guide for the Care and Use of Laboratory Animals

The *Guide for the Care and Use of Laboratory Animals*[20]was first published in 1963 and has gone through several revisions that mirror the changes that have occurred in the use and care of animals in research. The guide provides recommendations on the humane care and use of laboratory animals in biomedical research. The guide calls upon published reports, scientific principles, expert opinion, and professional experience in advising on the design and operation of humane animal care and use programs. Subjects covered include recommendations for institutional policies (regarding veterinary care, personnel qualifications, occupational health programs, use of hazardous agents, and animal restraint), laboratory animal husbandry (caging and housing systems, space recommendations, microenvironments and macroenvironments, food, bedding, water, sanitation, identification), veterinary medical care

programs (preventive medicine, animal procurement, quarantine, diagnosis and treatment of animal disease, anesthesia and analgesia, surgery and postsurgical care, and euthanasia), and construction guidelines for animal facilities.[21]

Association for Assessment and Accreditation of Laboratory Animal Care International

The Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC) International was founded in 1965 to accredit institutional animal care and use programs and facilities. AAALAC International uses the standards in the guide[20]as the benchmark for evaluating programs and facilities.

Site visitors to an institution inspect the facilities and collect information on animal care and use policies and procedures. The site visit report is presented to the AAALAC Council on Accreditation, which evaluates the program and makes recommendations on accreditation. Programs that meet the standards in the guide are given the status of accredited. In addition, recommendations are made on how to improve the program in order to achieve or retain accreditation.[22]

Biosafety in Microbiological and Biomedical Laboratories

Biosafety in Microbiological and Biomedical Laboratories[25]is a joint publication of the Centers for Disease Control and Prevention (CDC) and the NIH. It contains guidelines for handling infectious agents in the laboratory and for working with animals that harbor infectious agents. Infectious agents are classified into four risk groups. Characteristics of agents, laboratory practices, safety equipment, and facility design criteria are described for each biosafety level (BSL). Corresponding animal facility practices, safety equipment, and facility design criteria are given for each animal biosafety level (ABSL).[25]There is a distinction between risk group and biosafety level. Risk groups are based on the ability of an infectious agent to cause disease in humans and the severity of that disease. The selection of BSL is based on a risk assessment that takes risk group into consideration along with mode of transmission, procedures to be performed, personnel experience, and other factors.

Biosafety Level 1 and Animal Biosafety Level 1

Agents in BSL-1 are known not to cause disease in healthy humans. Standard animal care practices and routine microbiologic practices are used. Gloves and laboratory coats would typically be worn in animal rooms. Eyewear might be recommended if there was a potential for splash or aerosol. Special safety equipment is not required in the laboratory or animal facility. Standard animal facility design and laboratory facilities can be used. A hand-washing sink should be available in the animal facility. Exhaust air is discharged to the outside without being recirculated. Rooms should be under negative pressure with respect to the hallway, if possible.

Biosafety Level 2 and Animal Biosafety Level 2

Agents in BSL-2 are known to cause disease of varying severity in humans. Such agents are considered moderate in risk. Exposure can occur by autoinoculation, ingestion, percutaneously, or via the mucous membranes. Laboratory and animal facility practices incorporate BSL-1 practices for the laboratory and ABSL-1 practices for the animal facility with additional requirements reflective of increased risk, such as restricted access, posting of biohazard warning signs, implementation of sharps precautions, appropriate decontamination (preferably by autoclaving) of all infectious wastes and animal cages prior to washing, and delineation of any medical surveillance policies. In the laboratory, safety equipment consists of Class II biologic safety cabinets (BSCs) when a risk of aerosol or splashes exists during manipulation of

the agent and laboratory coats, gloves, and face protection as needed. Similarly, in the animal facility, safety equipment consists of containment equipment specific for the animal species and PPE such as laboratory coats or gowns, gloves, face and respiratory protection (surgical masks, dust or mist masks, or respirator as appropriate for the activity being performed and the hazardous agent being used), and eye protection. When infectious materials are being manipulated, or if aerosols or splashes might be created, a BSC or other physical containment equipment should be used. For the animal facility, the availability of an autoclave is recommended. In addition, a hand-washing sink in the animal room is required. Animal rooms should be maintained under negative pressure relative to adjacent hallways.

Biosafety Level 3 and Animal Biosafety Level 3

BSL-3 facilities and practices are intended for work with indigenous or exotic agents, agents that present a potential for aerosol transmission, and agents causing serious or potentially lethal disease. ABSL-3 facilities and practices are for working with animals infected with these agents. BSL-3 and ABSL-3 build upon the standard practices, procedures, containment equipment, and facility requirements of BSL-2 and ABSL-2.

The standard and special safety practices, safety equipment, and facility requirements are similar for BSL-3 and ABSL-3. Highlights of these are provided below.

A medical surveillance program, based on an appropriately conducted risk assessment, must be available for personnel working with infected animals. Immunizations should be provided if available. Consideration should be given to the need for collection and storage of serum samples. Information should be provided on the impact of immune status on susceptibility to infection. Individuals with immune dysfunctions should be encouraged to self-identify so that appropriate counseling can be provided.

Policies for the safe handling of sharps, such as needles, scalpels, pipettes, and broken glassware must be developed and implemented.

PPE must be utilized to reduce exposure to infectious agents, animals, and contaminated equipment. A risk assessment should determine the appropriate type of PPE to be utilized. Examples of PPEs that might be used include coverall suits; wraparound or solid-front gowns; gloves; eye, face, and respiratory protection; and boots, shoe covers, or other protective footwear.

A method for decontaminating all infectious materials (including animal tissues, carcasses, contaminated bedding, unused feed, sharps, and other refuse) must be available within the facility. Several types of decontaminating systems are available (e.g., autoclave or chemical disinfection).

Whenever possible, the manipulation of infectious materials, handling of infected animals, or procedures that generate aerosols must be conducted in Class II or Class III BSCs or other physical containment devices. When a procedure cannot be performed within a BSC, a combination of PPE and other containment devices must be used.

The use of containment caging systems to reduce exposure to aerosols from infected animals and bedding should be considered.

BSL-3 and ABSL-3 facilities have special engineering and design features, including:

- Restricted access

- Double-door entry comprising an anteroom/airlock and a change room

• Showers

• Inward directional airflow, which draws air from "clean" areas and toward "contaminated" areas

• Ducted exhaust air ventilation system with discharge of exhaust air to the outside

• No recirculation of exhaust air

• Availability of an autoclave convenient to the animal rooms

Biosafety Level 4 and Animal Biosafety Level 4

BSL-4 and ABSL-4 practices and facilities are used when working with dangerous and exotic agents where there is a high risk of life-threatening disease or aerosol transmission. Agents that are related to known pathogens in this group but have an unknown level of risk or transmission also should be placed in this category. Often there is no vaccine and possibly no therapy available for these agents. There are only a few facilities in the United States equipped to handle agents in this risk group.

The standard and special safety practices, safety equipment, and facility requirements are similar for BSL-4 and ABSL-4. Highlights of these are provided here.

There are two models for BSL-4 and ABSL-4 facilities:

• A cabinet laboratory, where agents are handled in Class III BSCs

• A suit laboratory, where personnel wear a positive-pressure protective suit

BSL-4 and ABSL-4 cabinet and suit laboratories have special engineering and design features to prevent microorganisms from escaping containment:

• Rooms in the facility must be arranged to ensure sequential passage through an inner (dirty) changing area, a personal shower, and an outer (clean) change room prior to exiting.

• An automatically activated emergency power source must be provided for the exhaust system, life support systems, alarms, lighting, entry and exit controls, BSCs, and door gaskets.

• A dedicated nonrecirculating ventilation system is required. The supply and exhaust components of the ventilation system must be designed to maintain the laboratory at negative pressure.

• Redundant supply fans are recommended. Redundant exhaust fans are required. Supply and exhaust fans must be interlocked to prevent positive pressurization of the laboratory.

• The ventilation system must be monitored and alarmed to indicate malfunction or deviation from design parameters.

• Class III BSCs must be directly and independently exhausted through two high-efficiency particulate absorption filters in series. Supply air must be provided in a manner that prevents positive pressurization of the cabinet.

Entry and exit to the facility are through clothing change and shower rooms. A complete clothing change (undergarments, pants, shirts, jumpsuits, shoes, and gloves) is required to enter the facility. All persons leaving the laboratory must take a personal body shower.

In suit laboratories, all procedures must be conducted by personnel wearing a one-piece positive-pressure suit ventilated with a life support system.

An occupational medical program must be provided. The program includes medical surveillance and immunizations for agents being used; collection and storage of serum samples from at-risk personnel; and a system for reporting and documenting laboratory accidents, exposures, and employee absenteeism.

Transfer of supplies and materials into the facility is generally through a double-door autoclave, fumigation chamber, or airlock.

All equipment and supplies taken inside the laboratory must be decontaminated before removal. Decontamination of equipment that cannot be autoclaved is by gaseous or vapor methods (e.g., vaporized hydrogen peroxide or gaseous chlorine dioxide).

Protocols for emergency situations (e.g., medical emergencies, facility malfunctions, fires, escape of animals within the laboratory) must be established.

All manipulations of infectious materials within the facility must be conducted in Class III BSCs. Decontamination of materials passing out of the Class III BSC(s) is through an interlocked double-door, pass-through autoclave, dunk tank, fumigation chamber, or equivalent decontamination method.

Centers for Disease Control and Prevention Guidelines

The CDC has published infection prevention guidelines for healthcare facilities that include recommendations regarding animals brought into such facilities.[26] Guidelines for animal-assisted activities and resident animal programs include precautions against nonhuman primates and reptiles for use in healthcare facilities. Animals should be healthy, well groomed, fully vaccinated, and well trained. Immunocompromised animal care personnel should avoid contact with animal feces, saliva, urine, or litter box material. Increasingly, animals are being brought into healthcare facilities as patients or research subjects to access imaging and oncology equipment. Under such conditions, the healthcare facility should develop specific policies to address this type of usage. Human healthcare facilities should be used only if veterinary facilities are unavailable. Animal care should be under the supervision of a licensed veterinarian. Patient care areas where invasive procedures are performed should be avoided for the treatment of animal patients. Animal procedures should be scheduled late in the day when human patients are not likely to come in contact with animals. Environmental surfaces should be disinfected after animals have been removed. Likewise, equipment should be disinfected or sterilized after animal contact, or disposable equipment and supplies should be used. Reusable medical and surgical instruments should be restricted for use only in animals.

Occupational Health and Safety in the Care and Use of Nonhuman Primates

Occupational Health and Safety in the Care and Use of Nonhuman Primates[27] specifically addresses the risks associated with exposure to nonhuman primates in biomedical research. It draws on the principles and practices in *Occupational Health and Safety in the Care and Use of Research Animals.*[14] Infectious and noninfectious hazards are discussed, and information on risk management is provided. Recommendations on medical treatment following exposure to nonhuman primate hazards are provided.[27]

VIRAL AGENTS

Macacine herpesvirus1 (formerlyCercopithecine herpesvirus 1 [CHV-1])(also known as B Virus)

B virus is the most significant infectious occupational health hazard in nonhuman primate research. B virus, an alpha herpesvirus closely related to herpes simplex virus, is carried by Asian and African monkeys in the genus *Macaca*. The agent has been found principally in rhesus (*M. mulatta*) and cynomolgus (*M. fascicularis*), but also has been isolated from bonnet (*M. radiata*), Japanese (*M. fuscata*), Taiwan (*M. cyclopis*), and stump-tailed (*M. arctoides*) macaques.[28,29,30]

Initial infections in macaques are usually asymptomatic; however, lesions may occur in the oral, ocular, and genital regions. Lesions consist of fluid-filled vesicles on the dorsum of the tongue, the mucocutaneous border of the lips, the inside of the cheeks, or the genitalia. These blisters rupture, scab over, and eventually heal in 7 to 14 days. The virus is shed from active lesions. In addition, conjunctivitis may be observed. Once infection is established, B virus remains latent in the trigeminal or lumbosacral sensory ganglia. Systemic disease is rare in macaques.[28]

Transmission to humans occurs through exposure to contaminated animals (e.g., scratches, bites, splashes to mucosal membranes, contact with infected animal tissues) or contaminated equipment (e.g., needlesticks, sharp cage parts). Direct correlation cannot be made between the extent of animal-associated injury and the likelihood of infection.[28]The incubation period from exposure to symptomatic disease ranges from weeks to years (due to reactivation of latent infection). In most cases, death has occurred from 2 days to 6 months after infection. The virus propagates within the peripheral nervous tissue (ganglia) and spreads to the spinal cord and eventually the brain.[28]

Human cases of B virus are considered rare, despite its prevalence in the host species and the large numbers of macaques used in research.[31]Early-stage symptoms include influenza-like illness and headaches. On some occasions, vesicles have formed near skin wounds exposed to contaminated animals or equipment. Progression of the disease involves symptoms attributed to central nervous system infection, including alterations in vision, seizures, and respiratory failure.[29]Without treatment, mortality in infected humans is estimated to be approximately 80 percent.[28]

Detection of the virus in nonhuman primates and humans is performed by serologic testing and virus isolation at the B Virus Research and Resource Laboratory (Georgia State University, Atlanta, GA) or at the Central Public Health Laboratory (London, United Kingdom). The presence of serum antibodies indicates infection with the virus but not necessarily shedding of virus. Viral culture is often unreliable because of intermittent shedding of the virus by infected monkeys and the difficulty in recovering virus in tissue culture. Polymerase chain reaction (PCR) and reverse-transcriptase (RT)-PCR also can be used for detection of virus.[28,32]

Postexposure prophylaxis with antiviral therapy has been efficacious when instituted within 72 hours after exposure; however, studies of antiviral dosing and time courses primarily have been performed in rabbits.[28]

Guidelines for prevention of herpes B virus infection in monkey handlers have been published.[28]Because overt clinical disease is rarely observed in macaques infected with B virus, viral shedding occurs in the absence of observable indicators. All macaque monkeys should be treated as though infected, and their bodily fluids and soiled cages should be handled as if they were contaminated. Macaque monkeys

should be used for research purposes only when clearly indicated. Activities involving the use of tissue, cells, blood, or serum from macaques should be performed using ABSL-2 practices. BSL-2 practices are recommended for B virus culture activities, and BSL-3 facilities are recommended for propagation of virus or work with animal models of B virus infection. B virus is classified as a select agent by the federal government and requires CDC registration for use in research.[25]

Access to areas where macaques are housed or used should be limited to those who are trained in procedures to avoid risk of infection. Personnel who might contact macaque monkeys or their bodily fluids must wear protective clothing, including long-sleeved gowns or laboratory coats, latex gloves, eye goggles or face shields, and surgical masks. Monkey handlers must be trained in the proper methods of restraint and in the use of protective clothing. Restraining or handling fully awake macaques is not recommended unless required by the approved scientific protocol. Fully awake macaques should be handled only with arm-length leather gloves, and animals should be removed from cages by the use of pole and collar restraint.

The most critical period for the prevention of B virus infection is during the first minutes after the exposure occurs.[28]Bites or scratches from macaques should be immediately and thoroughly scrubbed with antiseptic soap and water. Any exposure should be reported immediately to the appropriate supervisory personnel. The placement of monkey bite, scratch, and needlestick first aid kits in primate housing facilities has been recommended. Employees working with macaques should receive training in first aid procedures for treatment of wounds potentially contaminated with B virus.[28]Wounds sustained from working with monkeys or equipment contaminated with monkey saliva or urine should be scrubbed vigorously for 15 minutes with gauze sponges soaked in antiseptic soap. If eye splashes occur, rinse the eyes immediately with water at an eye wash station or sink for 15 minutes. If water is not available, use ocular irrigating solution. Prompt medical attention should then be sought.

Any wounds sustained from macaque exposure should be cultured for B virus, and blood should be drawn for B virus serologic testing. The patient should be educated about the clinical signs of herpes B virus infection.[28]The wound should be examined every other day for the first week and then weekly through the end of the fourth week. The wound should be assessed for vesicle formation, itching, pain, and numbness. After an observation period of 2 to 3 weeks, a second serum sample should be drawn to determine whether serum antibodies have developed.

Laboratory evaluation of the monkey associated with the human injury is an important component in treatment of the patient. At the time of exposure, the monkey should be examined for the presence of lesions; serum samples should be drawn; and viral cultures should be collected from bilateral conjunctiva, buccal mucosa, and genitalia. A convalescent serum sample should be collected 3 weeks after injury. A rise in B virus-specific antibody suggests active infection at the time of the employee's injury. The monkey colony personnel, veterinary and husbandry staff, and involved physicians should receive the results of the veterinary evaluation.[28]

If clinical signs develop, the patient should be referred to a physician who is knowledgeable about evaluation and management of B virus infections.

Hantavirus

Hantaviruses comprise a genus in the family Bunyaviridae. Each type of hantavirus, of the approximately 21 that have been identified, is associated with rodent hosts, including rats, mice, and other wild rodents. As hantaviruses continue to be isolated from the estimated 2,000 species of murid rodents,

there may be greater numbers of zoonoses characterized in laboratory animal rodents.[33] Hantaviruses have not been reported in personnel working in contemporary animal facilities with commonly used laboratory rats (*Rattus norvegicus*) and mice (*Mus musculus*).

Hantaviruses cause asymptomatic infections in rodent hosts. The virus is shed in the saliva, urine, and feces of persistently infected rodents for months.[34] Transmission occurs through inhalation of infective aerosols, wound contamination, conjunctival exposure, and ingestion.[13] Infectious virus also may be present in the blood and organs of infected mice.[35] Rat cell lines have been demonstrated to be a source of infective virus.[36]

Two syndromes has been associated with hantaviral infection of humans: hemorrhagic fever with renal syndrome (HFRS) and hantavirus cardiopulmonary syndrome (HCPS). HFRS has been documented in numerous animal facility personnel, particularly in Japan, France, the United Kingdom, Singapore, and Belgium.[13] The severity of HFRS is related to the strain of virus involved. Clinical symptoms include acute onset of fever with lower back pain. HCPS, caused by the Sin Nombre virus (reservoir: deer mice *Peromyscus maniculatus*), is characterized by fever, myalgia, and gastrointestinal distress.[37] HCPS has not been associated with rats of the genus *Rattus* or mice of the genus *Mus*. The incubation period in humans averages from 2 to 4 weeks.[38]

Recommendations for management of hantaviruses in laboratory animal facilities have been published elsewhere.[25,33] In general, potentially infected tissue samples should be handled in BSL-2 facilities in accordance with BSL-3 practices. Experimentally infected rodents that do not excrete the virus can be housed in ABSL-2 facilities and handled using ABSL-2 practices. BSCs and other containment devices should be used whenever there is a high potential for generating aerosols. Studies in which virus is inoculated into *Peromyscus maniculatus* or other permissive species should be conducted at ABSL-4.

Exposure to rodents and their tissues should be prevented by using proper PPE. Treatment of symptoms in humans involves supportive care.

Lymphocytic Choriomeningitis Virus

Lymphocytic choriomeningitis virus (LCMV) is an arenavirus. It exists in the wild mouse population in all areas of the world. Infection has been reported in many potential laboratory animal species, including mice, rats, hamsters, guinea pigs, chinchillas, rabbits, dogs, nonhuman primates, swine, and chickens. Wild mice are the principal reservoir of infection for susceptible species. Laboratory mice, hamsters, marmosets, and tamarins have been implicated in transmission of disease to humans.[8,9,39,40]

Disease in infected animals is dependent on age, strain and dose of virus, and route of inoculation.[41] In adult mice, the disease is self-limiting. However, neonatally infected mice develop persistent, lifelong infections. These animals act as carriers and shed virus particles throughout their lives.[8,9,39,42] Athymic and severe-combined immunodeficient mice can harbor silent, chronic infections.[43]

Infection may be transmitted by several routes: direct skin or mucous membrane contact with the infective secretions (urine, feces, saliva), ingestion or inhalation of aerosolized virus particles from the animal room or cage, parenteral exposure, and contact with contaminated bedding material or infected ectoparasites.[14,42] In addition, tissue culture cell lines and transmissible tumors can become

contaminated and harbor the virus. These can serve as either a means for transmission of the agent into mouse colonies or for infection of laboratory workers. Transmission by aerosolization is a particular hazard for pregnant women; LCMV has been shown to induce abortion in early stages of gestation and is a teratogen when a fetus is exposed in later stages of pregnancy.[42,44]

Influenza-like illness (ILI) due to LCMV infection has occurred in animal technicians, research personnel, and veterinarians. Headache, fever, and myalgia are often noted, and clinical symptoms may progress to aseptic meningitis. In immunocompetent individuals, ILI is most common clinical syndrome, but there have been reports of neurologic symptoms or more serious systemic illnesses. Immunocompromised patients are at a higher risk of illness and including reports of hemorrhagic fevers.[42]The incubation period ranges from 1 to 3 weeks.[13]

Infection can be detected in mice by virus isolation assays and PCR analysis of target tissues. Contamination of cell and tumor lines can be determined by inoculation of susceptible mice with the tumor or cell line and subsequent detection of antibodies to the virus in infected mice, or with PCR analysis of cell or tumor lines. In humans, serologic detection of rising antibody titers in paired sera is considered diagnostic.[38]

Prevention of the disease in humans is fostered by proper hygiene, including the use of latex or other medical gloves and subsequent hand washing after rodent handling.[8]ABSL-3 practices and facilities are recommended for activities with a high potential for production of aerosols, for manipulation of quantities of infectious material, or for work with infected animals.[25]Surveillance is performed by testing rodent serum for viral contaminants endemic in the colony; infected colonies may be freed of the virus by depopulation and cesarean rederivation.[38]

Orf (Contagious Ecthyma; Contagious Pustular Dermatitis)

Orf disease is caused by a parapoxvirus and occurs worldwide in sheep and goats. Typical lesions in these animal species consist of proliferative pustules around the lips, gums, nostrils, teats and udders, and urogenital openings.[14]Interdigital and coronet lesions may be associated with laminitis. The disease in goats tends to be more severe than that in sheep.[45]The virus is transmitted, from animal to animal and animal to human, most commonly by direct contact with exudates from lesions and sometimes through fomites.[14]The virus is highly resistant to desiccation and can persist in clinically apparent lesions.

In humans, the disease begins as a solitary maculopapular or pustular lesion on the hands, arm, or face that progresses to a weeping, proliferative, umbilicated nodule.[14]The incubation period ranges from 3 to 6 days. Treatment is typically not undertaken because the disease is self-limiting over 3 to 6 weeks.

Personnel working with sheep should wear gloves and possibly other protective clothing that covers exposed skin. Laboratory sheep and goats may be given preemptive vaccinations with live attenuated virus or scarification with a suspension of infective scab material.[14,46]In addition, it is recommended to disallow entry of clinically affected animals into established research herds.

Rabies

Rabies is caused by a rhabdovirus and can infect most mammalian species, including laboratory dogs, cats, ferrets, livestock, and nonhuman primates. Initial signs of disease in animals vary considerably from agitation and confusion to ataxia and paralysis. Death can occur in animals within 2 to 7 days of illness.[45]

Suspect animals should be quarantined for 10 days after any bite injury to humans to observe for behavioral signs suggestive of infection that would warrant euthanasia.[47]Animals that meet criteria for true rabies virus infection should be necropsied, and the brain tissues should be analyzed for viral antigen.[45]

Transmission is sustained by the bite of a rabid animal or inoculation of infective saliva into mucous membranes or fresh wounds. Although no cases of rabies have been reported in animal facility personnel, it is important to monitor for this zoonotic pathogen in facilities that use random-source or conventional animals of unknown health background. In humans, rabies can cause headaches, fever, and malaise that can progress to encephalomyelitis and death due to respiratory paralysis. The incubation period can be as short as 10 days, but averages 3 to 8 weeks in length. Detection of viral antibody and viral isolation from affected tissues is necessary for diagnosis. Treatment is usually unrewarding.

Rabies in high-risk animal personnel is often prevented by pre-exposure immunization. Immediate and thorough wound disinfection is recommended. Postexposure administration of human rabies immunoglobulin at the wound site may be beneficial. National standards address prevention of rabies virus for persons in the United States.[48,49]Verification of current rabies vaccination should be mandatory for dogs, cats, and ferrets that enter the existing animal colony.

RICKETTSIAL AGENTS

Cat Scratch Fever

*Bartonella henselae*is the etiologic agent of cat scratch fever. Cats, and occasionally dogs, are the reservoir of this agent. Infection is usually asymptomatic, though reproductive failure in female cats and peliosis hepatitis in dogs have been reported.

The cat flea is the principal vector that spreads infection within the animal population; however, flea-to-human transmission is unlikely. Infection typically occurs in humans following bites or scratches from healthy young cats and occasionally dogs. This agent is an emerging pathogen among immunosuppressed individuals and warrants appropriate precautions in animal facilities.[50,51]

Most human infections occur between September and February and follow a cat bite or scratch, usually from pet animals.[14]No cases within a laboratory animal setting have been documented. After traumatic inoculation, an erythematous papular lesion develops, followed by a vesicle and scab. Although the local lesion resolves within a week, regional lymphadenopathy develops several weeks later. The lymph node may rupture, and the patient may exhibit fever, malaise, anorexia, headache, and splenomegaly. More serious complications, though less common, include periocular lymphadenopathy, conjunctivitis, central nervous system involvement, osteolysis, hepatitis, and pneumonia. If the patient is immunocompromised, severe systemic or recurrent infection, including bacillary angiomatosis, can develop.[14]The incubation period ranges from 3 to 14 days for development of the primary lesion and as long as 50 days for development of lymphadenopathy.

Definitive diagnosis requires culture of the organism from a lesion. However, it is common to accept a combination of clinical signs, history of contact with cats, histopathological examination of biopsy tissue, and failure to isolate other causative agents from cultures as evidence of infection.[14]Systemic cat scratch disease should be included in the differential list for patients presenting with fever of unknown origin and abdominal pain, especially if there is a history of contact with a cat or kitten.[52]

Personnel handling cats should be instructed in proper restraint techniques and should use protective clothing to prevent scratches and bites. Wounds sustained from cats in particular should be thoroughly disinfected.

Q Fever

*Coxiella burnetii*is the etiologic agent of Q fever. Both wild and domestic species act as hosts. Within the animal facility, sheep, goats, and cattle are the most important reservoir hosts.[8,53]Dogs and cats also have been reported to serve as reservoir hosts. Infected animals are generally asymptomatic; however, in cases of severe infection, abortion and reproductive failure may occur.

Due to concerns of *Coxiella burnetii*as a bioterrorism agent, it has been added to the list of reportable diseases.[54]

The organism is shed in the urine, feces, milk, and birth products of domestic sheep, goats, and cattle. Transmission to humans often follows exposure to fetal membranes, birth fluids, and stillborn animals. Inhalation of infective tissues may occur during parturition. Ixodid and argasid ticks can serve as reservoirs and vectors of the organism.[45]The incubation period ranges from 2 to 3 weeks. Acute infection in humans results in ILI, with headaches, fever, and myalgia. Pneumonia is one of the primary manifestations of acute Q fever.[55,56]Infection in pregnant women can lead to spontaneous abortion. Additionally, women who contract Q fever during pregnancy are at a higher risk of developing chronic infections than the general population.[55]Chronic infection may result in granulomatous hepatitis or endocarditis. In patients with underlying valvular disease, chronic infection may manifest as culture-negative endocarditis. Chronic infection can occur within a few months or even years after an acute infection.[55,56]Diagnosis can be made through detection of increasing antibody titers between acute and convalescent samples or by identifying the organism in infected tissues or body fluids via PCR or culture.[54,55]Doxycycline is the recommended treatment for Q fever and is most effective when given early in the course of diease.[55]

To prevent exposure to the organism, obtain only male sheep or nonpregnant female sheep for experimental purposes. Sheep also may be purchased from known Q fever-negative flocks. Employees should wear protective clothing, such as surgical masks, disposable gloves, shoe covers, and gowns or laboratory coats, when handling sheep and goats. Due to the risk of aerosol transmission, it is helpful to ensure adequate ventilation in ruminant housing areas and to keep these animals physically separated from humans. If pregnant ewes must be used for research purposes, an N95 respirator and eye protection are recommended when working with the animals during parturition and lactation or when performing surgery.[55]

BACTERIAL AGENTS

Campylobacteriosis

Multiple strains of *Campylobacter*have been isolated from animal species used in biomedical research, including pigs, chickens, sheep, dogs,[57]cats, ferrets,[58]hamsters,[59]and nonhuman primates.[60]Clinical disease in animals may be absent; however, young animals may exhibit more severe clinical manifestations.[45]Symptoms of overt watery to mucohemorrhagic diarrhea, fever, reduced appetite, and vomiting may occur. Abortions and stillbirths have been linked to *C. fetus*. Prevalence of *Campylobacter*in contemporary laboratory nonhuman primate colonies may be low.[61]One report of transmission from asymptomatic laboratory-housed coyotes has been documented.[62]

The organism is shed in feces. Transmission is through fecal-oral routes. Enteritis in humans has been associated with exposure to domestic animals, sheep, and pigs. Infection often is asymptomatic, but clinical syndromes can include abdominal pain, fever, lethargy, vomiting, and diarrhea. Signs typically resolve in 2 to 5 days but may extend up to several weeks.[63]In rare cases, more severe outcomes, including reactive arthritis, febrile convulsions, Guillain-Barré syndrome, and meningitis, may occur. The incubation period ranges from 1 to 10 days.

Diagnosis is made through detection of the organisms in stool samples. Supportive care, including hydration and electrolyte replacement, is recommended for treatment of symptomatic cases.

There is a low to moderate risk of transmission if proper sanitation measures are followed by animal care staff and laboratory personnel.[64]Laboratory animals that are suspected as carriers of infection should be identified and may be treated with antibiotics.

Capnocytophagosis and Pasteurellosis

Bite and scratch injuries sustained from laboratory animal species represent an important occupational hazard for animal facility personnel and research workers. The diverse bacterial flora that inhabits the oral cavities of animals, dogs and cats in particular, may be pathogenic to humans. Two agents of zoonotic importance are *Capnocytophaga canimorsus*(formerly DF-2) and *Pasteurella multocida*.

Multiple reports of *C. canimorsus*transmission to humans from their pet dogs and cats exist; however, no cases have been reported in animal facilities. If humans are exposed to this bacterium, clinical case reports indicate that splenectomy and alcoholism may be strong predisposing factors for overt disease.[65]

Clinical symptoms of *C. canimorsus*infection include cellulitis, fever, and septicemia, which may progress to endocarditis, arthritis, meningitis, and death. The incubation period ranges from 1 to 5 days after exposure. The bacteria can be cultured or identified within neutrophils. Treatment includes administration of penicillin G.[38]

Animal reservoirs for *P. multocida*include rabbits, cats, dogs, and pigs. Rabbits often show signs of rhinitis and otitis, but many may be healthy carriers. Cats and dogs have a subclinical infection that is asymptomatic. Pigs can develop atrophic rhinitis if coinfected with other bacterial strains.

Humans are commonly exposed to *Pasteurella*by bite wounds and potentially by aerosolization. Cellulitis, erythema, and swelling have been reported. Humans also may experience pneumonia, meningitis, and fatal congenital complications.[66]Bite and scratch lesions can be cultured for isolation of the bacteria. The incubation period is as long as 24 hours. Wound cleansing, debridement, and treatment with antibiotics

is recommended.[67] Rabies and tetanus vaccination should also be considered for patients with animal bite wounds.

Prevention of bites and scratches from multiple species requires appropriate training for handling diverse animals with care and confidence. Gloves and other means of protective equipment should always be worn when handling animals.

Chlamydiosis

Many laboratory animal species can serve as hosts for Gram-negative *Chlamydia* and *Chlamydophila* species, including sheep, goats, dogs, cats, guinea pigs, frogs, and poultry. These animal hosts can be asymptomatic carriers or may exhibit symptoms that are species specific.[13] Sheep and goats may have pneumonia, enteritis, and reproductive complications; dogs may have pneumonia and endocarditis; cats and guinea pigs may experience conjunctivitis and keratitis; frogs may exhibit lethargy, edema, petechiation, and disequilibrium.

Transmission to humans is through direct contact with animals or their tissues, particularly birth products of ruminants and other mammals. Inhalation of contaminated aerosols is a hazard for those working with poultry.

Disease occurs sporadically in animal facility personnel. ILI with conjunctivitis, pneumonia, and septicemia has been reported. Pregnant women are susceptible to febrile illness, congenital infection, and abortion. Following exposure, the incubation period is 1 to 4 weeks. The agents can be detected by analysis of paired sera with increasing antibody titers.

Treatment with tetracycline or doxycycline may be beneficial. Direct contact and inhalation of aerosols should be prevented through the use of appropriate PPE.

Helicobacteriosis

Multiple strains of *Helicobacter* have been isolated from a variety of animal species, including humans. Many of the same strains of *Helicobacter* have been found in the gastrointestinal tracts of both animals and humans. Fecal-oral transmission is suspected; however, further studies are necessary to determine whether animals truly serve as a source of the bacteria for zoonotic transmission to humans. *Helicobacter pylori* can infect humans and cause gastritis, but animal contact has not been implicated as a cause of the infection.[8,68] *H. suis* and *H. pullorum* have both been implicated in human disease.[69,70]

Leptospirosis

Infection is caused by spirochete bacteria of the genus *Leptospira*, including *L. canicola, L. hardjo, L. icterohaemorrhagiae, L. interrogans* serovar *ballum, L. pomona*, and *L. sejroe*. Multiple animal species can serve as reservoir hosts, including mice, rats, gerbils, hamsters, dogs, cats, ruminants, swine, and nonhuman primates. Different diseases are seen in the different animal species following infection. In mice, infection is asymptomatic. Dogs may succumb to hepatic and renal disease, with hematuria.[71,72] Ruminants may have reproductive failure, whereas nonhuman primates may experience abortions and icterohemorrhagic disease.[73,74] To detect the organisms in host species, serology can be performed to assess rising antibody titers. In addition, culture and PCR of infective urine can be performed.

Transmission to humans occurs through oral and aerosol exposure to contaminated urine, reproductive tissues, and fetal tissues. Organisms also can infect humans through abrasions in the skin and mucosal membranes.

Disease in humans is variable. Mild ILI symptoms may progress to severe infection with renal, hepatic, and pulmonary, or meningeal involvement. Weil's disease (jaundice) has been documented in animal facility personnel. The incubation period ranges from 4 to 19 days. Infection is diagnosed through serology or isolation of leptospires from blood, urine, or cerebrospinal fluid.

Treatment involves antimicrobial therapy with penicillin, cephalosporins, tetracyclines, or erythromycin.[38]

Exposure to contaminated animals is prevented through the use of PPE that covers skin and mucosal surfaces. Animal vaccines are available but may not prevent transmission to humans.

Rat Bite Fever

The most common etiologic agent of rat bite fever is *Streptobacillus moniliformis*, a pleomorphic, Gram-negative rod. *Spirillum minus*, a spiral-shaped, Gram-negative rod, also has been associated with infections following rat bites but much less frequently.[8,75]

Wild and laboratory rats are the principal reservoirs, though the organisms also have been isolated from mice, gerbils, squirrels, weasels, dogs, cats, and nonhuman primates. These agents are considered part of the normal nasopharyngeal flora of rats. Clinical disease in rats and other hosts is rare but has been reported.[75',76]Detection involves isolation of the agents from the oral cavity, nares, or conjunctival sacs and identification by culture or PCR. Animal inoculation may be used for isolation of *S. minus*.[38]

In the research setting, human infections are most often associated with rat bites. Transmission also can occur after exposure to infective urine or secretions from the mouth, nares, or conjunctival sacs. Although clinical disease occurs infrequently, it must be considered in the treatment of rat bite injuries sustained by animal care and research personnel. Infection with *S. moniliformis*can lead to flulike symptoms, regional lymphadenopathy, and arthritis. Infection with *S. minus*can result in a distinctive rash with red to purple plaques.

The incubation period for *S. moniliformis*is less than 10 days; however, *S. minus*has an incubation period of 2 weeks to 3 months. Diagnosis requires isolation and culture of the organism from the primary lesion, lymph node, blood, or synovial fluid.

Treatment begins with thorough cleansing of the wound. Penicillin or tetracyclines can be administered for 7 to 10 days.[38]Tetanus prophylaxis also should be considered after bites from rodents.[12]Transmission of the agents from rodent bites can be prevented through the use of PPE, such as gloves, and by thorough disinfection of sustained wounds. In addition, personnel should be trained in proper restraint techniques when handling rodents.

Shigellosis

*Shigella*spp., including *flexneri, dysenteriae*, and *sonnei*, are Gram-negative anaerobes. These organisms infect nonhuman and human primates and cause diarrhea, dehydration, and weight loss. Severe infections in monkeys also may lead to gingivitis, air sacculitis, and abortions.[77]The organisms can be cultured from fecal material placed on appropriate microbiological media.

Transmission of the agent to monkeys initially is from humans, with secondary spread to other monkeys and back to humans by the fecal-oral route. Humans infected with the bacteria also develop varying degrees of diarrhea, with fever, nausea, and potential autoimmune complications.[78]The incubation period lasts from 1 to 4 days. Antimicrobials can be administered based on culture and sensitivity results.

Appropriate PPE should be worn at all times when working with nonhuman primates (see *M. herpesvirus*1 discussion).

Tuberculosis

In animals, tuberculosis is caused by acid-fast rods of the genus *Mycobacterium*, including *M. tuberculosis, M. bovis, M. avium-intracellulare, M. avium*subsp. *paratuberculosis, M. kansasii, M. simiae, M. chelonae*, and *M. marinum*. Many species of animals are susceptible to tuberculosis, including nonhuman primates, dogs, cats, pigs, ruminants, chickens, and pigeons. Within the animal research setting, nonhuman primates, fish, and amphibians are the animals most likely to be infected with mycobacteria.[14]

Aquatic species commonly carry mycobacteria. These infections are usually subclinical in fish unless environmental stress or other diseases cause clinical symptoms. Humans can acquire cutaneous infections from handling animals or aquaria or soiled water. Lesions are usually nodules or granulomas on the skin or arms that can be diagnosed by PCR. It is recommended that personnel that work with aquatic species wear gloves that prevent skin contact with animals and water and that they wash hands after working with animals or aquaria.[79]

Monkeys do not carry usually acquire tuberculosis from other sources including humans, other animals, or environmental sources. However, once infected, transmission readily occurs between monkeys with secondary spread back to humans.[13]

Susceptibility to tuberculosis varies among all species of nonhuman primates. Macaques are the most susceptible, whereas New World primates are the least susceptible. Nonhuman primates usually become infected in their country of origin through contact with infected humans.[14,80]

The disease in nonhuman primates can be asymptomatic, but animals may succumb to acute death. Pulmonary disease is a common presentation, though intestinal and cutaneous tuberculosis with draining tracts have been reported. Nodular lesions may form in multiple organs, including vertebrae, brain, and spinal cord.

Laboratory nonhuman primates are routinely tested on arrival to the facility and thereafter for exposure to mycobacterial species. In quarantine, monkeys are usually tested every 2 weeks; however, in established colonies, quarterly testing is recommended. Intradermal skin testing (Mantoux testing), using tuberculin, is performed in captive monkeys. Positive test reactors are retested for confirmation and may undergo pulmonary radiography. Animals suspected of having tuberculosis are generally euthanized and necropsied to establish a definitive diagnosis. Mycobacterial culture is difficult and may take 4 to 8 weeks for confirmation. Serology and PCR also may be used for detection. False-negative skin testing may occur due to concurrent disease or immunosuppression. Rarely, animals with positive test results may be treated to control the disease.[14,80]

Transmission of tuberculosis is primarily by infective aerosols, but fecal-oral routes of transmission have been documented. Individuals working with nonhuman primates have an increased risk for development of a positive tuberculin skin test. In addition, personnel with tuberculosis pose a substantial risk for nonhuman primates. In humans, pulmonary, meningeal, and visceral organs and other body systems may be infected by disease agents. Progressive pulmonary disease may be fatal. Crohn's disease has been linked to *M. avium*subsp. *paratuberculosis*infection.[81]The incubation period ranges from 2 to 10

weeks for development of primary lesions or skin test positivity.[38] Diagnosis can be assisted by skin testing of personnel, PCR, RT-PCR, and pulmonary radiography. Treatment of disease is based on established antimicrobial protocols, including combination treatment with isoniazid, rifampin, and pyrazinamide.[38] Increasingly, drug-resistant mycobacterial strains are being recognized.

Occupational health programs for personnel working with nonhuman primates should include regular intradermal skin testing of at-risk facility personnel (usually annually or semiannually), training in the use of PPE, and education on tuberculosis. Individuals who develop a positive skin test should be referred to a physician for follow-up. They should be reassigned to work tasks other than nonhuman primate areas until it has been determined that they are free of tuberculosis.[14,80]

MYCOTIC AGENTS

Zoonotic fungal infections are uncommon in animal research. The most significant are dermatomycoses caused by *Microsporum canis, Trichophyton mentagrophytes*, and *Trichophyton verrucosum*. Potentially, animals obtained from random source dealers may serve as a source for infection, which presents with crusts and ulcerative skin lesions. Transmission to humans is through direct contact with infected animals. Humans develop self-limiting skin lesions, often referred to as "ringworm," that spread outward circumferentially. Treatment of the disease is accomplished by thorough cleansing with soap and water; fungicides may be applied topically. Prevent transmission through the use of appropriate PPE, particularly disposable gloves.

PROTOZOAL AGENTS

Toxoplasmosis

Cats are the reservoir host for this parasite, *Toxoplasma gondii*.[8] Cats are infected after ingestion of infected prey animals and begin to shed oocysts within 3 weeks. Oocysts take more than 24 hours to become infective after shedding. Transmission to humans occurs through ingestion of infective oocysts. Although most human infections are subclinical, infected pregnant women are particularly at risk for congenital infections, which may result in severe neurological damage to the fetus.[8]

Immunosuppressed individuals are more likely to exhibit clinical symptoms, including lymphadenopathy, fever, and pneumonia. Transmission of this pathogen can be greatly diminished, if not eliminated, through management techniques within the facility. Litter boxes should be emptied completely on a daily basis, which eradicates fecal exposure to infective oocysts. Prevent wild rodent entry into the facility so that infection is not introduced to the laboratory cat population.[8]

Cryptosporidiosis

Many animal species can serve as reservoirs for *Cryptosporidium* spp.[8] Although infection may be asymptomatic in animal hosts, cats, dogs, ruminants, monkeys, and other species may develop intractable diarrhea. The disease can be severe in immunosuppressed animals. Transmission to humans is likely fecal-oral. Humans predominately exposed to livestock have contracted this infection. Disease may be asymptomatic or result in profuse watery diarrhea. The incubation period averages 1 week. Treatment with antimicrobials is often unrewarding; therefore, supportive fluid therapy should be administered. Prevent direct contact with contaminated excreta through the use of PPE.

Parasitic Agents

The risk of infection with helminth parasites originating from laboratory animals is insignificant. However, infestations with ectoparasites (e.g., mites, fleas, and ticks) derived from laboratory animals have been reported. Facility personnel may have moderate to severe, yet transient, dermatitis, eczema, pyoderma, or painful bites. More substantial consequences may result if personnel are bitten by ectoparasites harboring bacterial, rickettsial, or viral agents of human disease.[13] To control for parasitic infections within laboratory animal colonies, prompt treatment and elimination of infestation of animals and their habitats are warranted. Personnel should treat affected lesions with topical or systemic parasiticides and control exposure through the use of PPE.

Conclusions

The use of animals in biomedical research carries with it some risk of infection with zoonotic agents carried by the animals themselves or infectious agents administered to animals as part of the experimental protocol. Several significant disease-causing agents still exist in some species of animals. Herpes B virus is a cause of fatal encephalitis and is carried by macaque monkeys. Other nonfatal infectious agents that might be encountered include lymphocytic choriomeningitis, orf, cat scratch fever, Q fever, tuberculosis, and rat bite fever.

Exposure of personnel is most likely to occur in association with laboratory procedures involving the pathogen, vector, or animal-handling procedures such as necropsy, injections, handling, and restraint. When working with live animals, it is important to assess whether the pathogen or vector is shed from the infected animal and by what route, if known. In the case of handling killed animals, tissues, or fluids, personnel must be appropriately trained in methods to prevent exposure and infection.

Regulations regarding animal use require that research studies address prevention and treatment issues with infectious pathogens prior to initiation of the experimental work. Risk reduction and control are accomplished through the use of well-documented techniques and equipment such as PPE, BSCs, the use of disease-free animals, and the implementation of an occupational health program for personnel handling animals.

Future Trends

Several areas of infectious disease research will increase in prominence in the future.

Recent outbreaks of emerging infectious diseases such as West Nile virus, severe acute respiratory syndrome, monkeypox, and avian influenza all point to a trend for new disease agents to arise in animal populations and make the transition to the human population.[82] Research into emerging diseases is increasing worldwide and will pose new challenges with regard to development of animal models and methods of containment and management.

Another area of increasing emphasis in infectious disease research is that of bioterrorism involving infectious agents such as smallpox virus and anthrax bacteria. It should be noted that the majority of infectious agents identified as potential terrorist weapons are zoonotic agents. The use of these agents in research will undoubtedly increase in biomedical research institutions in the future as studies on pathogenesis and prevention are pursued.

Finally, increased use of infectious agents as vectors for the delivery of foreign genes to animals for the study of genetic diseases and their treatment through gene therapy can be expected. These agents, which have been genetically altered to render them nonpathogenic and replication defective (e.g., adenovirus and vaccinia virus), are used to transfect animals with the genes being studied. Although these agents are presumed to be noninfectious, until they have been used in humans and demonstrated to be safe, they must be assumed to be potentially infectious. In addition, the genes being transferred pose a potential risk to personnel, and their effects must be considered in risk assessment. In general, ABSL-2 facilities and ABSL-3 conditions should be followed.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Animals Visiting in Healthcare Facilities

Author(s): Kathleen (Kit) Darling, MS, CIC
Veterinary Medical Teaching Hospital

Texas A & M University
College Station, TX

Published: October 3, 2014

Declarations of Conflicts of Interest: Kathleen (Kit) Darling currently serves on the board of directors for Aggieland Pets With A Purpose (President) and Aggieland Humane Society. No financial compensation is received.

Abstract

People benefit from human–animal interaction socially, psychologically, and physiologically. In healthcare-related situations, programs for animal visitation, animal-assisted activities, animal-assisted therapy, and service animals are intended to assist in returning patients to wellness and independence. Healthcare facilities must establish animal and handler guidelines and program-specific infection prevention policies to provide a safe environment for animals, handlers, and patients. Healthcare providers need to understand and abide by the laws for service animals and persons with disabilities.

Key Concepts

- Animal-assisted activities, animal-assisted therapy, and visitation in healthcare facilities benefit patients socially, psychologically, and physiologically.
- The potential risks of animals in healthcare facilities include patient allergies, phobias, animal-caused injuries, and zoonoses.
- Healthcare facilities can provide a safe environment for both humans and animals by establishing guidelines and policies for the animal, handler/volunteer, patient, and infection prevention.
- Animals must meet defined health and temperament requirements to be accepted into animal-assisted therapy programs.
- When a personal pet visit is a necessary treatment intervention for the health and well-being of the patient, policies and guidelines should be established to ensure the safety of the pet, the patient, and

others in the healthcare facility.

- Service animals differ from therapy animals and personal pets in their health-related roles.
- Healthcare providers must understand and abide by the rights of persons with disabilities accompanied by service animals.

Background

Animals serve in numerous aspects of human life, providing companionship, many kinds of assistance, and livelihood.[1]Research shows that people benefit from the human–animal interaction socially (increasing interaction with others), psychologically (reducing stress and anxiety and increasing motivation and sense of well-being), and physiologically (decreasing blood pressure and possibly decreasing cardiovascular risks).[2,3]One of the main objectives of healthcare is to return patients to wellness and independence.[4]Today, animals may be used to accomplish this objective through visitation, animal-assisted activities (AAA), animal-assisted therapy (AAT), and service functions. This chapter addresses the challenges of animals in healthcare facilities and offers help to those facilities in developing guidelines and policies to provide a safe environment for both humans and animals. Areas covered include animals certified for AAA/AAT, personal pets, service animals, infection prevention and safety measures, patient suitability, and animal suitability.

Basic Principles

Animal-assisted interventions (AAIs) intentionally incorporate animals as part of a therapeutic or wellness improvement process. This includes AAAs in which the same animal does not necessarily visit the same person every time, and the effect of the animal visits on the participant is not formally measured or documented. It also includes AAT, a treatment modality in which the same animal visits the same patient each time, and the patient's progress as a result of the specific therapy is documented and measured.

The importance of unconditional love, the value of touch, the energy derived from acts of unselfish kindness, and the security of companionship all enhance and improve people's quality of life and health.[5,6]Animals providing visitation, AAA, and AAT, and those that are personal pets and service animals, may fulfill these conditions. Understanding the definition of each type of animal and its function is helpful in establishing policies and guidelines for animals in healthcare facilities.

AAAs are "meet and greet" activities that provide opportunities for recreation, motivation, and education. AAAs are not directed at specific therapeutic goals.[7,8]An example of AAA is animal visitation. The animal initiates contact with the patient, and the direction of the visit is determined by the patient's needs at that particular time. Animal visitation may be effective in increasing the patient's responsiveness, providing a pleasurable experience, enhancing treatment such as decreasing the need for pain medication, and helping to keep the patient in touch with reality.[5,6]Visitation may help with short-term goals. The animal visit may help foster rapport and initiate communication.[5]Visitation may take place one on one or in a group setting with a single animal or group of animals. Animal visitation may decrease loneliness and improves a patient's well-being.

AAT is directed toward specific goals in which the animal meets specific criteria as an integral part in the treatment process. A certified therapist or healthcare professional facilitates the interaction between the patient and the animal to improve physical, cognitive, emotional, and social functions.[7,8] An example of AAT is a patient brushing a dog to improve physical movement of the hand and arm.

AAT can provide multiple benefits, including fine and gross motor skills; verbal, tactile, and auditory stimulation; verbalization skills; ambulation and equilibrium; instruction-following and decision-making; memory recall; and concentrated and extended attention span. Physical, occupational, recreational, and speech therapy programs may use AAA/AAT and animal visitation.

"Service animal" is a legal term defined by the Americans with Disabilities Act (ADA). In March 2011, the ADA defined service animals as dogs that are individually trained to do work or perform tasks for a person with a disability.

Webster's II Dictionary defines pet as "an animal kept for pleasure or companionship" and a "handler" as "a person who trains or controls an animal."[9] The handler may be the animal's owner or a person who has trained the animal to obey him or her. The person who brings an animal for AAA/AAT or animal visitation may be referred to as "handler/volunteer" in this chapter. Animals that provide AAA/AAT and visitation are usually pets. A service animal is not considered a pet because it is specially trained to help a person overcome the limitations caused by the disability.[10] The term "handler" is also used when referring to the person with disabilities who has a service animal.

Animal-Assisted Activity/Animal-Assisted Therapy

AAA/AAT is used in many healthcare facilities, including outpatient, acute care, rehabilitation, and extended-care facilities. AAT uses specially trained therapy animals. These animals are not a patient's pets. Dogs are the most frequently used. Other animals used include cats, birds, guinea pigs, and rabbits. In a guideline from a Working Group sponsored by the Public Health Agency of Canada and the Centre for Public Health and Zoonosis, University of Guelph, on animals visiting healthcare facilities, it was recommended that suitable animal species for AAA and AAT programs should be limited to domestic companion animals that are household pets.[11]

Animals participating in AAA/AAT and animal visitation programs must be screened and trained to ensure that they have the temperament to tolerate the equipment and environment in a healthcare facility. Abnormal behavior of an animal can easily dislodge tubes and wires or injure patients.[4]

A number of national and local animal-assisted organizations certify animals for AAA/AAT. These organizations require the animal to undergo a health screening for parasites, skin and dental problems, and necessary immunizations (per individual state law) by a veterinarian. The organization does a temperament evaluation to test the animal's aptitude for basic obedience and response to stress. Dogs must respond to the commands "heel," "sit," "down," and "stay." The temperament test is designed to evaluate the animal's behavior under conditions that they may experience when in healthcare facilities. They include reactions toward strangers, loud or startling noises, crowding, restraining hugs, and being patted or handled in a clumsy manner.[11] Cats, rabbits, and guinea pigs must be willing to remain in a basket or on a blanket when held. Certified animals commonly carry liability insurance through the certifying organization.[1] Animals that participate in AAT programs attend additional training with

equipment used in the therapy activities and the environment where the therapy is done. These animals may also participate in AAA or animal visitation programs. Physical, occupational, recreation, and speech therapy may use certified animals. States may have regulations on animals visiting healthcare facilities. The facility must check on state regulations when deciding to adopt the recommendations in this chapter.

ANIMAL GUIDELINES[1,4,11]

1. Animal must be a domestic companion animal. Exclude the following species, which may pose a higher risk of causing human injury or infection:
    a. Nonhuman primates
    b. Reptiles and amphibians
    c. Hamsters, gerbils, mice, and rats
    d. Prairie dogs, hedgehogs
    e. Animals that have not been litter trained or for which measures cannot be taken to prevent exposure of patients to the animal's excrement
2. Animal must not be a current resident of an animal shelter, pound, or similar facility and must be in a permanent home for at least 6 months.
3. Animal must be at least 1 year old.
4. Animal must be registered or certified for AAA/AAT.
5. Animal must pass health, skills, aptitude, and temperament tests.
6. Records of the animal's health must be up to date.
7. Animal must be appropriately restrained or on a short leash. Identification badges, bandanas, vests, and such may be required.
8. Animal must never be left alone with a patient.
9. Animals should be restricted from food preparation, service areas, and other high-risk areas identified by the healthcare facility.
10. Animals must not have been fed raw foods of animal origins within the previous 90 days.

VISIT GUIDELINES: INFECTION PREVENTION AND SAFETY

Most of the literature published about animals in the healthcare setting has focused on the benefits, and little has been published about the actual risks the animals pose. Some studies have examined the potential risk of animals in healthcare facilities such as allergies, phobias, zoonosis, and animal-caused injuries.[12,13]

Zoonosis (the transmission of disease between animals and humans), infection prevention, and safety are the major challenges that the healthcare facility will have to address when allowing animals to interact with patients and staff.[6]Animals can transmit infectious diseases to humans, and likewise,

humans can transmit infectious diseases to animals. Animals can become transient vectors or carriers of potential human pathogens and could be responsible for cross-infection.[4]

More than 200 zoonotic diseases have been documented, but only around 35 are thought to be potential risks from animals used in AAA or AAT.[12]See Table 122-1 for the most common zoonotic

diseases, compiled by the National Association of State Public Health Veterinarians. The focus of infection prevention policies for animal programs must be on good hand hygiene and the use of healthy, clean, and well-behaved animals, and designate appropriate patient populations to minimize the risks for transmission of infectious agents. After the introduction of AAT in Huntington Memorial Hospital,

Pasadena, California, there was no zoonotic infections reported during 3,281 dog visits to 1,690 patients in a 5-year period.[5]In studies at two children's hospitals, neither has found increased rates of infection.[12,13]

Although many healthcare facilities have adopted AAI programs, there has been inconsistent application of infection prevention standards.[11,14]It is essential that more attention be given to the infection prevention components of AAI programs. Animals participating in AAI programs may act as carriers or reservoirs for infectious agents, thus spreading pathogens between patients and healthcare personnel. These animals may be more likely to acquire multidrug-resistant organisms than most pets. Currently, the literature review does not indicate that hospital infection rates have increased in facilities that have AAI programs.[15]Even though this is encouraging, there may be a lack of sufficient reporting or assessment of surveillance methods.[14]A report in the United Kingdom implicated a resident cat colonized with methicillin-resistant *Staphylococcus aureus* (MRSA) as a reservoir for an outbreak in a rehabilitation geriatric ward.[16]A prospective study monitored two groups of dogs participating in AAI in healthcare settings versus other settings. The results suggested that dogs visiting healthcare facilities had a greater risk of acquiring MRSA and *Clostridium difficile*than dogs visiting in other settings. The risk was greater for the dogs that licked patients or received treats from patients in healthcare facilities.[17]Proper infection prevention procedures are warranted at all times to minimize the risk of transmission between humans and animals and animals and humans.

In addition to the risk of infection, other concerns about animals in healthcare facilities include phobias, allergies, cleanliness, and animal-induced injuries (bites and scratches). Patients must be asked if they would like to visit or interact with the animal. Measures should be taken to control the animal's dander, which may be the source of some allergies. Measures include bathing the animal with allergen-reducing shampoo, wiping the animal with a pet wipe prior to the visit, and having the animal wear a T-shirt, vest, or other protective clothing. However, animal visits should not be allowed for patients with phobias or known allergies to the type of animal visiting in the facility.

If the animal has an elimination accident, gloves should be worn to remove the debris and clean up the area and hand hygiene performed after glove removal. Any organic debris and paper towels should be placed in a plastic bag in a trash container, similar to the disposal of diapers. After the area is cleaned, it must be disinfected with the facility's approved product, following the label instructions for appropriate concentration and contact time.

Bites and scratches are the major concern for animal-induced injuries. To minimize the risk of these injuries, it is important that the animals used for AAA and AAT undergo temperament testing by a person or group who is experienced in assessing animal behavior. The healthcare facility AAA/AAT program coordinator must obtain verification that the animals have had temperament evaluation.[11,14]

Healthcare facilities should develop and implement infection prevention guidelines and develop policies to minimize the potential risks associated with having animals in healthcare facilities. These should require that animals be of good temperament, well-groomed, and healthy and that that their handlers be educated on infection prevention practices, including hand hygiene. The following infection prevention and safety guidelines should be in place:

1. The healthcare facility develops policies and guidelines for the safety of the patients and animals involved in visitation, AAA, and AAT. The healthcare facility should designate a person or persons

to the implementation of the policies and coordinate animal–human interactions and act as a liaison to the animal handlers visiting the facility.
2. Animals participating must have a temperament test (behavioral assessment) by an experienced person or recognized group.
3. Animals are required to be bathed within 24 hours before the visit.
4. Animals may wear a shirt, vest, or other protective clothing to control allergies. Wiping the animal with a baby or pet wipe will help control dandruff.
5. Animals must have clean ears.
6. Animals must have nails that are short with no rough edges. Animals must be trained not to scratch the patient. For additional protection, animals may wear protective foot coverings.
7. Animals must be healthy and current with immunizations, including rabies vaccination and others required in the state in which the healthcare facility is located. An annual physical examination by a licensed veterinarian should include dental and dermatological evaluation. Animals should be free of communicable diseases and parasites and be on a flea control program.
8. Animals must be free of any skin condition or wounds.
9. Handlers must ensure that animals do not lick or come in contact with a patient's open wound or devices.
10. If an animal is allowed in a patient's bed, a barrier such as a disposable cloth, towel, or sheet can be placed between the animal's coat and the patient's linen.[1]The barrier is removed and discarded when the animal leaves.
11. Animals are kept on a short leash or in a carrier or basket. The use of retractable leashes is discouraged.
12. The animal's handler/volunteer must be healthy and free of communicable diseases. The facility is strongly encouraged to consider a recommendation to handlers that they receive annual influenza shots and may be able to offer the vaccine to handlers for free as part of the annual flu vaccination program.[11]
13. When the visit or interaction is finished, the patient must wash his/her hands or use an alcohol hand sanitizer.

PATIENT SUITABILITY GUIDELINES

Care must be taken to evaluate whether a patient is suitable for AAA/AAT or animal visitation. Special care is needed for patients with allergies, open wounds, or immunosuppression, and visitation should not be allowed in these circumstances unless the facility has developed approved criteria that must be met, including a requirement for physician evaluation, approval, and order for the visitation.

The following are patient suitability considerations.

1. Ask the patient if he/she wants to interact with the animal or has allergies or phobias to animals.
2. Exclude patients with allergies to animals; open wounds or burns; open tracheotomy; immunosuppression (as defined in the facility AAA/AAT program); agitation or aggression; or transmission precautions or isolation of any kind; or exclude others for reasons as defined by facility-specific patient populations or infection risks.[18]
3. Exclude patients who are infected with tuberculosis, *Salmonella, Campylobacter, Shigella*, *Streptococcus A*, MRSA, ringworm, *Giardia*, and amebiasis.[4]
4. Special requirements:
    a. An altered level of consciousness or coma may require verbal consent from a family member.

   b. Pediatric patient interactions necessitate verbal consent from parent or guardian and written consent for therapy.
   c. Wounds (not open) or healed burns must be covered during the visit, and the animal must not come in contact with these areas.
   d. If visitation is allowed for a patient with tracheotomy, the area must be completely covered.
   e. If visitation is allowed in the intensive care environment, the patient's nurse must provide guidance and assistance regarding the best way for the animal to approach the patient and avoid the equipment.[6]

5. Hand hygiene must be practiced before and after animal contact, including handler, patient, staff, and visitors.[11] It is considered most efficient to provide handlers with a portable bottle of hand sanitizer that they can offer to all who pet the animal.

HANDLER/VOLUNTEER GUIDELINES

The animal's handler/volunteer is important in making the animal's interaction with the patient safe and beneficial. The following are handler/volunteer guidelines:

1. Work with the staff to determine how the animal's interaction will benefit the patient.
2. Neither the handler nor the animal may visit if either is ill. The program should give guidance regarding when visitations can be restarted after an illness.[11]
3. The handler/volunteer must make sure that the animal has a chance to eliminate before entering the facility.[19] The handler must pick up the elimination in a plastic bag and deposit it in the trash and wash hands.
4. The handler/volunteer must focus on the animal and remove the animal from any situation where the animal is too stressed. Be sure the animal has breaks for water and elimination needs.
5. A bite or scratch incident must be reported and investigated and, upon review, may be grounds for dismissal from the visitation program per program policy.

PERSONAL PETS

Personal pets are a source of comfort to patients. A personal pet visit may be the best treatment intervention for the health and well-being of a patient in special situations. Personal pet visits are usually used for long-term or terminally ill patients. Personal pet visits require just as stringent a policy as visitation by certified animals. *Personal pets are allowed to interact only with their owners, handlers, and healthcare staff assisting with the visit*. These animals may not have undergone an evaluation of their temperament and obedience; thus, their behavior with others may be unpredictable. The following guidelines are recommended:[1]

1. The pet must be bathed within 24 hours before the visit.
2. A record of current vaccination should be provided prior to approval of the visit.
3. The pet must be on a short leash or in a carrier. Use of a retractable leash is not allowed.
4. The pet must be escorted into and out of the facility by designated staff.
5. The pet must not be allowed to interact with other patients or visitors.
6. Visits are limited per facility policy based on predetermined factors (facility specific).
7. The handler and patient must be informed prior to the visit that they may be asked to remove the animal from the facility at any time.

SERVICE ANIMALS

Service animals differ in their roles from animals that provide AAA or AAT. In September 2010, the Department of Justice revised the final regulations for the ADA for title II (state and local government) and title III (public accommodations and commercial facilities). The ADA defines a service animal as a dog that is trained to do work or perform tasks for a person with a disability. Some examples of the tasks or work may include guiding people who are visually impaired, alerting people who are hearing impaired, alerting or protecting a person who is having a seizure, pulling a wheelchair for a person who is unable to do so, calming a person with posttraumatic stress disorder, reminding a person with mental illness to take prescribed medication, or performing other duties. The ADA does not consider dogs whose sole function is to provide comfort or emotional support to be service animals. Service animals are not pets. Only dogs are recognized under titles II and III, which allow them to accompany people with disabilities in areas where the public is allowed. In a hospital, a service animal would be allowed in patient rooms, clinics, examination rooms, or cafeterias. Hospitals may exclude service animals from operating rooms or burn units where the animal's presence could compromise a sterile environment.

Some additional rules from the ADA related to service animals include:

- Service animals must be harnessed, leashed or tethered unless these devices interfere with the animal's work or the person's disability prevents using these devices.
- If it is not obvious what service an animal provides, the staff may ask only the following questions:
  - Is a service animal required because of a disability?
  - What work or task is the dog trained to perform?

    The staff cannot ask the person with a disability for medical documentation, special identification card for the dog, or documentation of the dog's training, nor can staff require the dog to demonstrate its ability to perform the work or task.
- Access cannot be denied to a person with a service animal because of allergies or fear of dogs. If a person has allergies to dog dander or is afraid of a dog, accommodations should be made by assigning them to different locations in the room or different rooms in the facility.
- A person with disabilities can be asked to remove the service dog only if the dog is out of control and the handler is unable to bring it under control or if the dog is not housebroken.
- Service animals are allowed in the public area of a business that sells and prepares food even if state and local health codes prohibit animals on the premises.
- Staff is not required to provide care or food for a service animal.

The ADA has added a new and separate provision for miniature horses that have been individually trained to do work or perform tasks for people with disabilities. Miniature horses usually range in height from 24 to 34 inches (measured at the shoulder) and weigh between 70 and 100 pounds. When reasonable, entities covered by the ADA must modify their policies to permit miniature horses. The following assessment factors are to assist entities in determining whether miniature horses can be accommodated in their facility:

- Is the miniature horse housebroken?
- Is the miniature horse under the handler's control?
- Can the facility accommodate the miniature horse's type, size, and weight?
- Does the miniature horse's presence compromise legitimate safety requirements for the safe operation of the facility?[20]

Additional information concerning the ADA and service animals is on the ADA Website.

Conclusions

The human–animal bond has existed since humans began domesticating animals. Numerous studies have shown that people who value the human–animal bond can benefit physiologically, psychologically, and socially. Increasingly, animals are being used to treat acutely and chronically ill patients. Animal visitation, AAA, AAT, and service animals can provide better health and well-being to many. Although rare, the potential risks and legal liability for accidents and injuries to patients, staff, or handlers with animals in healthcare facilities exist. Healthcare providers must address the risk and liability issues by establishing guidelines and policies for animals in healthcare facilities. Guidelines and policies for animals, patient suitability, infection prevention, safety, and handlers/volunteers can provide for a safe environment for both humans and animals. After completing a study of programs involving canine visitation to hospitals in Ontario, Lefebvre and colleagues[21] recommend closer involvement of healthcare personnel with AAA and AAT programs to ensure that protocols are properly developed and implemented. Healthy, immunized, even-tempered, well-trained animals and maintenance of good hygiene practices help provide a safe environment. Each facility should establish written guidelines and polices for animal visitation, AAA, and AAT. Healthcare providers must understand their rights and obligations to persons with disabilities who are accompanied by service animals. Not only is welcoming a person with a service animal into a healthcare facility required by law, it is also good for public relations.

Table 122-1 Zoonotic diseases of importance in the United States, 2010

Disease	Agent	Means of transmission to humans	Most common species associated with transmission to humans[165,166]	Nationally notifiable human (H) or animal (A) cases	Severe or prolonged infectio usually associated with immunosuppressic
Acariasis (mange)	*Sarcoptes scabiei, Notoedres cati*, and other species of mites	Contact	Dogs, cats, horses, goats, sheep, swine, birds	No	No
Anthrax	*Bacillus anthracis*	Contact, aerosol, vector	Cattle, sheep, goats, horses	H, A	No
Avian influenza	Highly pathogenic avian influenza viruses	Contact, aerosol	Poultry, pet birds	H, A	No
Babesiosis	*Babesia microti* and other species	Vector	Cattle, rodents	A	Yes
Baylisascariasis	*Baylisascaris procyonis*	Contact	Raccoons	No	No
Bordetella bronchiseptica infection	*Bordetella bronchiseptica*	Aerosol	Dogs, pigs, rabbits, guinea pigs	No	Yes
Brucellosis	*Brucella melitensis, Brucella abortus, Brucella suis, Brucella canis*	Contact, aerosol	Goats, cattle, swine, dogs, horses	H, A	No

Campylobacteriosis	*Campylobacter jejuni, Campylobacter fetus, Campylobacter coli*	Contact	Cattle, sheep, goats, pigs, dogs, cats, birds, mink, ferrets, hamsters	No	No
*Capnocytophaga canimorsus*infection	*Capnocytophaga canimorsus, Capnocytophaga cynodegmi*	Contact	Dogs, cats	No	Yes
Cat scratch disease	*Bartonella henselae*	Contact	Cats	No	Yes
Chlamydiosis (mammalian)	*Chlamydophila abortus, Chlamydophila felis*	Aerosol, contact	Sheep, goats, llamas, cats, cattle	No	No
Contagious pustular dermatitis (orf or contagious ecthyma)	Parapoxvirus	Contact	Sheep, goats	No	No
Cryptococcosis	*Cryptococcus neoforms*	Aerosol	Pigeons, other birds	No	Yes
Cryptosporidiosis	*Cryptosporidium parvum*	Contact	Cattle (typically calves)	H	Yes
Dermatophilosis	*Dermatophilus*congolensis	Contact, vector	Goats, sheep, cattle, horses	No	No
Dermatophytosis (ringworm)	*Microsporum*spp, *Trichophyton*spp, *Epidermophyton*spp	Contact	Cats, dogs, cattle, goats, sheep, horses, rabbits, rodents	No	Yes
*Dipylidium*infection (tapeworm)	*Dipylidium caninum*	Vector	Dogs, cats	No	No
Escherichia coli O157:H7 infection	*Escherichia coli*O157:H7	Contact	Cattle, goats, sheep, deer	No	No
Echinococcosis	*Echinococcus granulosus, Echinococcus multilocularis*	Contact	Dogs, cats, wild canids	A	No
Ehrlichiosis or anaplasmosis	*Ehrlichia*and *Anaplasma*spp	Vector	Deer, rodents, horses, dogs	H	Yes
Equine encephalomyelitis	Togaviridae (eastern, western, and Venezuelan equine encephalomyelitis viruses)	Vector	Birds, horses	H, A	No
Erysipeloid	Erysipelothrix rhusiopathiae	Contact	Pigs, fish, crustaceans, mollusks	No	No
Giardiasis	*Giardia intestinalis*(Giardia lamblia)	Contact	Thought to be highly species specific and rarely transmittedfrom animals to humans	H	Yes
Hantaviral diseases	Hantaviruses	Aerosol	Rodents	H	No

Herpes B virus infection	Cercopithecine herpesvirus 1	Contact	Macaque monkeys	No	No
Influenza A	Influenza A virus	Contact, aerosol	Poultry, swine, ferrets	H, A	No
Larval migrans: cutaneous (hookworm)	*Ancylostoma*spp	Contact	Dogs, cats	No	No
Larval migrans: visceral, ocular,neurologic (roundworm)	*Toxocara canis, Toxocara cati*	Contact	Dogs, cats	No	No
Leishmaniasis	*Leishmania*spp	Vector	Dogs, wild canids	A	No
Leptospirosis	*Leptospira*spp	Contact, aerosol	Rodents, pigs, cattle, sheep, goats, horses, dogs	A	No
Listeriosis	*Listeria monocytogenes*	Contact	Cattle, sheep, goats, pigs, birds, dogs, cats	H	Yes
Lyme disease	*Borrelia burgdorferi*	Vector	Small rodents, wild mammals	H	No
Lymphocytic choriomeningitis	Arenavirus (lymphocytic choriomeningitis virus)	Contact, aerosol	Mice, hamsters, guinea pigs	No	Yes
Monkeypox	Orthopoxvirus	Contact, aerosol	Nonhuman primates, rodents	A	No
Mycobacteriosis (nontuberculous)	*Mycobacterium avium*complex, *Mycobacterium marinum*	Aerosol, contact	Poultry, birds, aquarium fish, reptiles	No	Yes
Pasteurellosis	*Pasteurella multocida*and other species	Contact	Dogs, cats, rabbits, rodents	No	Yes
Plague	*Yersinia pestis*	Vector, contact, aerosol	Rodents, cats, rabbits	H, A	No
Psittacosis (human)or avian chlamydiosis (birds)	*Chlamydophila psittaci*	Aerosol, contact	Pet birds, poultry	H, A	Yes
Q fever	*Coxiella burnetii*	Contact, aerosol, vector	Goats, sheep, cattle, rodents, rabbits, dogs, cats	H, A	No
Rabies	Lyssavirus	Contact	Cats, dogs, cattle and other domestic animals; wild carnivores; raccoons; bats; skunks; foxes	H, A	No
Rat bite fever	*Streptobacillus moniliformis, Spirillum minus*	Contact	Rodents	No	Yes

*Rhodococcus equi*infection	*Rhodococcus equi*	Aerosol, contact	Horses	No	Yes
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Vector	Dogs, rabbits, rodents	H	No
Salmonellosis	*Salmonella*spp	Contact	Reptiles, amphibians, poultry, horses, swine, cattle, pocket pets, many species of mammals and birds	H	Yes
Sporotrichosis	*Sporothirix schenckii*	Contact	Cats, dogs, horses	No	Yes
Staphylococcosis	*Staphylococcus*spp	Contact	Dogs, cats, horses	H (vancomycin-resistant *Staphlococcus aureus*)	Yes
Streptococcosis	*Streptococcus*spp	Contact, aerosol	Swine, fish, other mammals	H (some forms)	No
Toxoplasmosis	*Toxoplasma gondii*	Contact	Cats	No	Yes
Trichuriasis (whipworm infection)	*Trichuris suis, Trichuris trichiura, Trichuris vulpis*	Contact	Dogs, swine	No	No
Tuberculosis, bovine	*Mycobacterium bovis*	Aerosol, contact	Cattle, swine, sheep, goats	H, A	No
Tularemia	*Francisella tularensis*	Vector, contact, aerosol	Rabbits, pocket pets, wild aquatic rodents,sheep, cats, horses, dogs	H, A	No
Vesicular stomatitis	Vesicular stomatitis virus	Vector, contact, aerosol	Horses, cattle, swine, sheep, goats	A	No
West Nile fever	West Nile virus	Vector	Wild birds	H, A	No
Yersiniosis	*Yersinia enterocolitica*	Contact	Swine, many species of mammals and birds	No	No

Data regarding nationally reportable diseases were obtained from the CDC's nationally notifiable infectious diseases list, the World Organization for Animal Health (OIE) notifiable animal diseases list, and the USDA APHIS reportable diseases list.167–169 Cases may also be notifiable at the state level; state veterinarians or state public health veterinarians should be consulted for current listings of reportable diseases in specific areas.

Used with permission.

Future Trends

Innovating and redefining the way we think about our healthcare treatments, policies, and guidelines are cornerstones to our success in healthcare. More research is needed on the human–animal bond; physiological, psychological, and social benefits of interactions with animals; and the potential and actual risks of zoonotic disease transmission. This, combined with improved infection prevention practices, will help healthcare providers establish better policies and guidelines for animals in healthcare facilities. Additional research is needed to determine whether animals are an important source of transmission of pathogens such as MRSA for humans or if most animals are colonized after contact with human carriers.[11] Does a clean, healthy, well-behaved animal pose a greater risk for the transmission of infectious agents than healthcare personnel or visitors to healthcare facilities? A study by Cole and Gawlinski[22] demonstrated that as a result of an animal visitation program, patients and staff reported feeling happier, calmer, more loved, and less anxious. Miller and Ingram[23] reported that AAT may be beneficial to individuals in the surgical waiting room by relieving stress. Enhanced guidelines and policies can be established as more research is published on the benefits and risks of animals in healthcare facilities.

International Perspective

Because the benefits of AAA/AAT can cross cultural and political borders, the elements regarding safety and patient benefit should be considered. However, one should also take into account any cultural and religious issues that may pose challenges when animals are involved in patient care areas.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Body Piercing, Tattoos, and Electrolysis

Author(s): Amanda (Robinson) Valyko, MPH, CIC

Infection Control & Epidemiology
University of Michigan Health System
Ann Arbor, MI

Published: October 3, 2014

Abstract

Body piercing, tattoos, and electrolysis are becoming more common. As these practices become more prevalent in society, healthcare facilities see patients with complications from these procedures, particularly in family practice and pediatrics. In some ways, body piercing, tattoos, and electrolysis carry some of the same risks as operative procedures. There is a risk of infection to both the client and the operator. Proper infection prevention practices are important to mitigate the risk of infection; however, little regulation exists in the United States and varies by state.

Key Concepts

- Identification of the processes involved in body piercing, tattoos, and electrolysis.
- Infectious risks related to body piercing, tattoos, and electrolysis.
- Medical considerations for patients with body jewelry.
- Infection prevention techniques for skin piercing procedures.
- Occupational exposure.

Background

Throughout history, people have adorned their bodies with art and jewelry to distinguish themselves. Such body decoration may indicate membership in various religious groups or tribes, but often tattoos or

skin piercings are used to express individuality. Skin may be used as a canvas to display unique artwork. There is currently an increased interest in body piercing and tattooing, predominantly among adolescents and young adults. Designs may run the gamut of possibilities—from elaborate creations that cover the entire skin surface, to simple well-hidden designs, to those created with crude nonsterile instruments as part of gang rituals or during incarceration. Facial tattooing is also performed to create permanent cosmetic makeup for women. Tattoos and piercings may represent attributes such as individualism, risk, sexual fantasies, and uniqueness, which are important for adolescents attempting to prove their individuality.[1]

As with other medical procedures, there are risks associated with skin and mucous membrane disruption that may or may not be immediately apparent. A certain proportion of complications are due to inadequate aseptic technique performed in the studio setting, but many are due to the client's individual health considerations and personal hygiene. It is important that a person considering a tattoo or body piercing investigate the studio and the person who will perform the procedure. All professional studios should provide the client with an aftercare information sheet, identifying appropriate disinfection practices and site care to reduce the chances of infection.

Many cities and states require that studios be licensed, which generally indicates that minimum requirements have been met and an inspection has been performed by a public health department. Unfortunately, at this time there are no standardized guidelines or requirements in the United States for practices or licensure. Although there is no way to effectively estimate the percentage of people that have adverse outcomes after tattooing, body piercing, or electrolysis, they are considered to be safe procedures when performed by trained professionals.

Basic Principles

BODY PIERCING

Two techniques may be used for skin piercing: utilizing a needle or using an ear-piercing (stud) gun. It is the official position of the Association of Professional Piercers (APP) that only sterile disposable equipment is suitable for safe body piercing.[2]

Studios that use the needle technique may purchase piercing needles from a specialty supply outlet or may use hypodermic needles with the hub removed for the skin piercing procedure. All needles must be sterilized before use. The diameter of the hollow-bore needles generally varies from 6 to 18 gauge, but smaller or larger needles may be used.[3]

Most piercings are done in a sequential fashion: The tissue is secured using tools such as special forceps or a needle-receiving tube or special hand positioning, and the needle is pushed through the tissue. A cork is often held on the exit site to support the tissue and to prevent injury to the client and piercer. Then, the jewelry is inserted, essentially pushing out the piercing needle. The needle is passed through the tissue and out the other side and is often pushed into a cork.

Ear-piercing guns (also called stud guns) hold the earring studs and use a trigger motion to force the stud into and through the earlobe. Ear-piercing guns cannot be effectively sterilized, and aerosolized blood from a previous client can contaminate the gun. If any part of the stud touches the contaminated gun, there is the possibility of transmitting bloodborne pathogens. The APP feels that most of the ear studs are not as sharp as needles, and therefore the force generated by stud guns causes more tissue

damage to the earlobe.[2] If an ear-piercing gun is to be used, one with a disposable sterile cartridge that holds the stud is highly recommended.[3] The disposable cartridge is removed after piercing the ears of a client, and the remainder of the gun should be wiped with 70 percent alcohol between clients. Shops that use ear-piercing guns with a solid head (no disposable cartridge) must use high-level disinfection practices on their equipment between clients, as indicated in the manufacturer's instructions. If a glutaraldehyde product is used, the shop should be monitoring the process with indicator strips and ensuring that adequate ventilation is available. Ear-piercing guns should only be used on the fleshy part of earlobes.

Jewelry used during skin piercing should be smoothly polished and designed to permit easy cleaning. Gold (14 to 18 karat), titanium, surgical steel, or niobium jewelry is most commonly purchased because these pieces can be effectively sterilized and are less likely to cause allergic reactions. The amount of time needed for tissue healing varies. The type of jewelry used, the movement of the body site, the quality of the procedure, and site care performed by the client all affect the healing process. Healing time for piercings generally ranges from a few months to a year, depending on the site, health of the client, and aftercare. Vascularity of the area and likelihood of trauma during healing also affect healing time. The APP believes that in some instances it may be inappropriate to perform even the most standard piercing.[2] The organization recommends that their members should refuse to perform a piercing that could be dangerous, ill suited, unsuccessful, or for which they are not trained.

TATTOOING

Although most of us are familiar with the concept of tattooing, a review of basic techniques may be helpful to understand the complications and risks of the procedure. Tattooing permanently deposits pigments into the skin at a depth of 1 to 2 mm to create a design. The tattoo artist may draw the design by hand or use a stenciled design that is copied onto the skin before tattooing. Fine needles held within an electric-powered tattoo machine puncture the skin several hundred times per minute. To create the colors of the design, the needles are dipped into tattoo pigments that are poured into individual cups or caps for each client. These pigments may be purchased in liquid form or may be prepared on-site from a purified powder. Because the needles puncture both the epidermis and the dermis, blood and excess pigment should be wiped away with tissue or paper towels during the procedure.[3] Immediately after tattooing, the skin swells slightly and a small amount of bloody to colorless body fluid comes to the surface. The swelling lasts for a few hours, but it generally takes about 2 weeks for the skin to heal completely.

An electric tattoo machine is a relatively simple device, consisting of a rotating motor in a handle, a stainless steel tube that the tattoo artist holds, and a needle bar that runs through the tube and contains 1 to 14 needles that protrude from the end of the tube by approximately 2 to 3 mm. The solid-bore tattoo needles are soldered onto the needle bar, and various needle configurations are used to produce different line thicknesses and to add shading. The needles used for tattooing present the highest risk for infection. It is difficult to sterilize needles for reuse due to difficulty in adequately cleaning them before sterilization. Sterile needles must be used for only one tattooing session, on only one client.[3] When performed by a skilled, conscientious professional, procedures for skin preparation, image transferring, skin lubrication, tattoo dye preparation, and skin preparation during tattooing use good infection prevention techniques similar to those used during minor surgical procedures. Recommended instrumentation, disinfection, sterilization, and safe sharps disposal protocols are identical to standard healthcare industry practices.

ELECTROLYSIS

Electrolysis is a method for permanently removing hair by inserting a needle into a hair follicle and applying an electric current. There are several different methods currently in use: galvanic, thermolysis, and a combination of galvanic and thermolysis referred to as the blend method. Galvanic electrolysis utilizes a direct current that is sent down the hair follicle on the needle that has been inserted. This destroys the root of the hair because sodium hydroxide is produced when the electrical current interacts with the saline in the tissue. Thermolysis utilizes a high-frequency alternating current that is also sent down a needle inserted into the hair follicle. This method works by producing heat that destroys the root of the hair. This method is more rapid than galvanic electrolysis, but it may not be suitable for thick hairs. The blend method combines the previous methods and many experts consider it to be more effective.[4]

Electrolysis needles are not intended to penetrate the tissue, but in some instances they may become contaminated with blood or body fluids. The American Electrology Association's Infection Control Committee has published Infection Control Standards for the Practice of Electrology that make recommendations regarding standard precautions, hand hygiene, cleaning and disinfection of equipment, and bloodborne pathogens.

Infectious Risks Related To Body Piercing, Tattoos and Electrolysis

It has become well recognized that tattooing and body piercing activities can transmit infectious diseases. There has also been evidence of infection transmission during electrolysis. The primary source of information comes from case reports. Although tattooing was not uncommon in the past, there has been a significant increase in its popularity in the last few decades. The peak age range for acquiring tattoos is between 14 and 22 years old, and the incidence among females has quadrupled in the past 20 years.[5]Among 12 to 18 year olds, it is estimated that 10 to 16 percent have tattoos and 33 to 50 percent have at least one piercing other than the earlobe.

TATTOOS

If proper infection prevention protocols are not followed, there is a significant risk of the spread of infection. People receiving tattoos in suboptimal environments are at greater risk of infection. The incidence of tattoos among incarcerated persons and gang members is generally high, as is the prevalence of infections with one or more bloodborne pathogens. One cannot assume that the skin piercing procedures transmitted all bloodborne infections, although some of these tattoos may have been applied using less-than-optimal techniques in a population with a high prevalence of viral hepatitis and human immunodeficiency virus (HIV). Prison tattoos have been created using ballpoint pen shafts, paper clips, sharpened guitar strings, or other pieces of metal. Lack of sterilization and skin disinfection also increases the likelihood of transmitting bacterial infections in the corrections system. The incidence of tattoos is noted to be higher among women who engage in prostitution, a significant source of infectious disease transmission both in Western cultures and in Africa.[6]

Although researchers have tried to evaluate the prevalence of Hepatitis C virus (HCV) infection in persons with body art, this has been more difficult to evaluate than other similarly transmitted diseases. Testing methods have improved; however, due to the incubation and manifestation of HCV, it can be difficult to determine when someone was infected. Hepatitis B virus (HBV) transmission has been much

easier to identify. Long and Rickman reviewed 17 case studies found in the literature from 1950 to 1980.[6]Clusters of new infections were almost universally due to the lack of effective sterilization of tattoo needles between clients. As a historical note, tattooists would dip the needles into alcohol and flame them for disinfection purposes. With the current availability of small autoclaves and disposable products, the risk of infectious disease transmission has been reduced in reputable businesses.

Although we now know that HBV is more easily transmissible than HIV, there is still the possibility that tattooing may transmit HIV.[6]A case report in *Clinical Infectious Disease*discussed the possibility of HIV transmission through body piercing.[7]Other potential risk factors were denied by the patient, but could not be excluded. Needlestick simulations have shown that solid-bore needles transmit as much or more blood than hollow-bore needles used for phlebotomy; 1.2 to 2.0 µL of blood was transmitted by 23- to 27-gauge suture needles passed to a depth of 0.5 cm.[8]The issue of needle sterilization is still the key to preventing transmission of disease.

Other infectious complications of tattoos found in the literature include both bacterial and viral infections. With the rise in community-associated methicillin-resistant *Staphylococcus aureus*(CA-MRSA), it is becoming more common to see skin and soft tissue infections caused by MRSA. There have been reports of MRSA skin and soft tissue infections related to unlicensed tattoo parlors in Ohio, Kentucky, and Vermont. The severity of infection ranged from cellulitis to bacteremia requiring hospitalization and intravenous antibiotics. The infections were linked to suboptimal infection prevention practices such as appropriate hand hygiene, skin antisepsis, and appropriate disinfection and cleaning of equipment and surfaces.[9]The risk of localized infection is easily understood, as the skin contains many normal commensal bacteria that may be carried into the punctured area, even if the site is well cleaned before the procedure, similar to surgical site infections. After the procedure, appropriate aftercare techniques should be discussed with each client; distributing printed copies of instructions are highly recommended. Not all skin infections can be blamed on the tattoo artist—appropriate site care in the home is equally important. Infection is more commonly seen in nonprofessional tattoos, but serious complications may occur after any skin puncturing procedure. Transmission of warts (papilloma virus) has also been reported after tattooing procedures.[6]

There is a possibility that dyes from tattoos may cause skin irritation during magnetic resonance imaging (MRI).[10]Case reports of people with tattoos that underwent MRI indicate minor reactions such as burns, swelling, and erythema. The reaction is usually temporary and sometimes a pressure dressing can be used to prevent tissue distortion.[11]Recommendations include asking patients if they have any tattoos, informing them of the risks, and monitoring them throughout their MRI. As a precaution, a cold compress can be used on the tattoo during the MRI.[12]

BODY PIERCING

Body piercing has also been associated with the transmission of infections. Although tattooing and body piercing differ in the amount of exposure to needles and in procedure times, many of the infections reported occur in the weeks and months after the procedure, similar to surgical site infections. In order to prevent infections, the jewelry and needles must be sterilized before skin penetration. Needles are always single-use. Piercing guns have been recognized as being potential vehicles for infection transmission. The guns are difficult to clean and sterilize and the motion causes more trauma to the client than a regular needle.[13]Aftercare is different for piercings, as various sites may take up to 6

months or longer to heal. One of the differences in procedures is that piercings may pass through mucous membranes and that the metal left in place may cause an allergic reaction.

Piercings Not Involving Mucous Membranes

Although a wide range of infectious complications from body piercing has been reported, most of the data involves ear piercing.[14] Bacterial infections may result from improper initial piercing technique or from poor hygiene. The organisms involved in most earlobe-piercing infections are often considered normal skin flora, including *Staphylococcus* and *Streptococcus* species. Higher ear piercings in the ear cartilage have been associated with more pathogenic organisms, including *Pseudomonas* species.[14] Many of the infections that occur after earlobe piercing do not result in a physician visit, as local site care or removal of the earrings often solves the problem. Eyebrow piercings have approximately the same risk factors for infection as earlobe piercing, but there is little information available on the incidence of infection. Navel and nipple piercings are also similar in tissue characteristics. Wearing tight or textured clothing may irritate the site, potentially increasing the risk of site infection. Multiple cases of atypical mycobacterium infections after piercing have been reported. Mastitis due to *Mycobacterium abscessus* has been reported after a nipple piercing,[15] *Mycobacterium flavescens* has been reported after an eyebrow piercing, and *Mycobacterium chelonae* has been reported after a navel piercing.[16] There are case reports of infective endocarditis that required treatment with intravenous antibiotics, and in some cases surgical intervention to replace heart valves; the infections resulting from navel, earlobe, and nipple piercings.[17] There has also been a case report of tetanus after a naval piercing.[7]

Facial and Oral Piercings

Piercings that involve mucous membranes are considered to have a higher risk for infectious complications, due to their dark, warm, moist environment, which generally contains more bacterial flora, including anaerobes and yeast. A variety of facial and oral piercings are becoming more common. Barbells are placed through the lower lip in the oral cavity, exiting through the skin above the chin. Tongue piercing is also increasingly popular with adolescents and younger adults. Pierced tongues are sometimes considered easier to conceal than facial piercings, which may not be permitted in some workplaces. These piercings may result in more serious infections even after the piercing site has healed. There are multiple reports of endocarditis related to tongue and lip piercings.[17] These infections occurred from weeks after the piercing to several months after the piercing. The dental literature contains many reports of traumatic injury due to the placement of metal barbells in the mouth. Some wearers tend to "play" with the studs, moving them around in their mouths and increasing the risks of periodontal injury (gingival recession, and mucogingival defects), chipped, cracked, and broken teeth. There are also reports of aspiration of oral jewelry.[18]

Tongue piercings may be particularly painful, and the tongue may remain swollen well after the piercing procedure. Even after healing, the stud may rub the roof of the mouth, causing hard palate erosion. Martinello and Cooney reported a brain abscess linked to a tongue piercing.[19] The young woman developed severe swelling of the tongue and a foul-tasting discharge. After 2 to 3 days, she removed the barbell stud, and the symptoms resolved. One month later the woman experienced headaches, fever, nausea, vomiting, and vertigo. A computed tomography (CT) scan of the head revealed a cerebellar abscess that required drainage and 6 weeks of antibiotic therapy.[19] In general, if a piercing becomes infected, the jewelry should not be removed until the area is healed. Removing the piece while the area is still infected can result in abscess formation.[20]

Aside from the noninfectious complications, the long-term effect of oral piercings is an increased risk for transient bacteremia, hematogenous spread of bacteria to other sites, and endocarditis. It is critical that patients with oral piercings routinely undergo comprehensive periodontal assessment; however, many of those with oral piercings do not see them as health hazards and are very reluctant to remove them.[21]

Nasal piercings, usually involving a ring through a nostril or through the nasal septum, carry an increased risk of localized infection. Wearers should be careful not to touch their noses or handle the jewelry with unwashed hands, as the nares can become colonized with staphylococcal species, particularly *S. aureus*. If the wearer has a cold, the nasal drainage and nose blowing irritates the site and may lead to bacterial superinfection.

Genital Piercings

Healthcare personnel probably have the least experience with genital piercings, and little information is available in medical literature. The APP tells us that the average genital piercing customer is a more informed consumer than the usual navel, ear, or tongue piercing client. Those who elect to get them usually have already received and healed at least one other piercing and are often more informed about the piercing process and aftercare.[2]There are several clinically unaddressed issues associated with genital piercings. Potential risks of infection may be increased if tissue trauma occurs during sexual activity or if a condom is ripped by jewelry. Of course, there is the possibility for transmission of sexually transmitted diseases if condoms are not used; however, this risk is not increased simply by the presence of piercings. The professional piercer should ideally provide information on personal hygiene issues to all clients.

Medical Considerations Related to Piercing

It is becoming more common for healthcare personnel to provide care for patients with body jewelry, and it is sometimes unclear whether removal of the jewelry is necessary. Removal of these items is sometimes required for radiological purposes, and removal is not usually difficult if the patient is able to assist with the opening mechanism. In an emergency situation, attempts at removal may cause unnecessary trauma to the site and distress to the patient. In a survey of 28 accident and emergency doctors, only six were able to accurately describe the opening mechanisms of all three commonly used types of jewelry.[22]Descriptions of the types of jewelry currently used are not generally available in the medical literature, but are provided in this chapter. As the number of people getting pierced or tattooed increases in any locality, it is likely that the healthcare community will need to become more familiar with these practices and their complications.

Oral and dental complications have been reported as a result of oral piercings such as tooth fractures, gingivitis, bleeding, and gingival recessions as well as aspiration of oral piercing jewelry.[18]

Persons with immune-compromising conditions are at a higher risk of infectious complications from a piercing. The APP recognizes that some potential clients may be at higher risk for infections and other complications if they obtain a piercing, and it recommends the following guidelines for their members to discuss with a client:[3]

• An individual with heart valve disease (e.g., mitral valve prolapse) should consult their physician for prophylactic antibiotics.

• If an individual has a heart murmur, diabetes, hemophilia, autoimmune disorder, or other medical condition(s) that may negatively influence the piercing procedure or the healing process, he or she

should consult a physician before deciding to have a piercing placed.

• If there is an obvious skin or tissue abnormality that may include but is not limited to rashes, lumps, bumps, scars, lesions, moles, freckles, and/or abrasions, piercings should not be performed in the area.

• If the client wants to pierce irregular or surgically altered anatomy or if the client is unsuited due to occupational, recreational, or environmental factors, it is recommended that the piercing not be performed.

• Surface-to-surface or other frequently unsuccessful (i.e., commonly rejected by the body) piercings should not be performed.

• If the client is pregnant or has impending plans to become pregnant and wishes to get a nipple, navel, or other piercing, it is advisable to refrain from piercing.

Edema and hematomas may occur after piercing procedures, due to tissue trauma. Improperly sized jewelry may irritate adjacent tissue, particularly larger, heavier pieces. Heavy jewelry or accidental pulling may lead to torn tissue, which may require surgical repair.[23]Sarcoid-like granulomas may form at a pierce site, usually in association with gold jewelry.[14]Site-specific complications reported include aspiration of oral/facial jewelry with airway obstruction; prolonged bleeding from areas with high vascularity; cellulitis of the submandibular, sublingual, and submental facial spaces; speech impairment; increased salivary flow; and obstruction of radiographs in the odontoid view on a cervical spine series in the evaluation of trauma.[14]

Noninfectious complications such as allergic reactions and tissue trauma are also associated with tattooing and body piercing procedures. Contact dermatitis from metal allergy associated with ear piercing has been widely reported. Nickel allergy has been the most common problem and usually presents as an eczematous rash.[23]Contact sensitivity to gold and silver has also been reported. Metals used in body piercing jewelry are usually surgical-grade stainless steel, solid 14 or 18 karat gold, niobium, titanium, or platinum.[14]

It is difficult to estimate the percentage of the population that has nontraditional (other than earlobe) piercings, and there is probably a wide variation in local rates. Some of the common hospital practices, such as urinary tract catheterization, intubation, and MRI, may be affected by the presence of body jewelry, and it is essential for healthcare providers to be able to identify that their patients may have metal devices in their bodies. With an increase in nontraditional sites, it is sometimes difficult for healthcare personnel to identify potential sources for some complications or infections, particularly if the patient does not report "intimate area" piercings. This can be a sensitive issue in minors when they are being interviewed with their parents present and may result in the patient neglecting to report a nontraditional piercing.

Anderson et al. state, "Urologists should perhaps be particularly aware of the seemingly bizarre practice of genital piercing, as their specialist knowledge may sometimes be required to manage the inevitable complications."[24]There are at least eight variations on genital piercing sites for men and five for women.[14,23]It is quite common for people to have multiple genital piercings as well as piercings at other body sites. Unique and significant complications can result from genital piercing, including endocarditis, paraphimosis, and urethral puncture.[14]It should be noted that urethral puncture is not a complication from the Prince Albert piercing, one of the most common male genital piercings. For this procedure,

jewelry will be placed through the urethra—it enters the urethral meatus and exits where the piercing is made on the underside of the penis at the juncture of the head and shaft. It is one of the quickest to heal, with the fewest complications.

Potential complications in pregnant women are not well defined in the literature at this time. Although nipple, navel, and genital piercing sites would obviously be affected by body changes, delivery, and nursing, the APP offers these helpful suggestions on body piercings during pregnancy:[2]

• Navel jewelry may be left in place. Some women leave jewelry in during their entire pregnancy and delivery. If during the pregnancy the piercing becomes uncomfortable, the jewelry can be replaced with Tygon or fluoropolymers such as PTFE, which are inert plastics, similar to thick fishing line. These will bend and flex with the changing body, be more comfortable, and are safer to wear. Once the pregnancy is over, jewelry may be replaced.

• Most women who have had a nipple piercing remove their jewelry for breastfeeding, which is appropriate. Some milk may come from the site of the piercing during nursing, which should not be harmful or problematic from a healed site. There is no special care recommended during pregnancy for healed piercings.

Jewelry Removal

Nurses and physicians often have to determine whether to remove body jewelry in the healthcare setting, and these decisions can be difficult. There is a misconception that all body jewelry should be removed. Consideration should be given, however, to the fact that once jewelry is removed, it may be impossible to place it back into the same site after the patient is discharged. The pierced patient may protest that jewelry should not be removed, particularly if they are aware of the common difficulty of reinserting jewelry that has been removed even for a short period of time and even from a well-healed piercing.

Body jewelry does not need to be removed in the majority of cases, but there are times when it is necessary in order to properly care for a patient. The most common scenario in which body jewelry must be removed is to obtain radiological studies. Metal jewelry can obstruct accurate readings of radiographs and CT scans and should be removed from the area being studied.[25]Patients should be questioned about piercings prior to obtaining radiological tests, as the presence of metal jewelry may not be obvious. Because of the magnetic field, all jewelry must be removed when a patient must undergo MRI. Jewelry needs to be removed for CT scans only if it is in the area being studied. Traditionally, all jewelry should be removed when a patient is having surgery.

In some cases, jewelry in genital piercings may need to be removed to perform urethral catheterization of the bladder. Nipple piercings and surface piercings of the chest may cause additional injury to the patient or caregiver if defibrillation is necessary and the paddles are placed directly over the jewelry.[26]

Defibrillation should not be delayed for any reason,[27]but if the need is anticipated, jewelry should be removed to prevent burning and arcing. The jewelry may also be wrapped in cloth tape to help decrease any contact with an electrical current.

If it has been determined that body jewelry should be removed, healthcare providers should be made aware of the techniques necessary to accomplish this task. There are three basic types of body jewelry: the captive bead ring, the barbell stud, and plugs. Patients can sometimes be a valuable resource for how to remove jewelry, but in many instances they remain unaware of the procedure because they never anticipated the need for removal.

Removal of the Captive Bead Ring

Step 1: Lubricate the piercing with a small amount of saline and insert a hemostat into the ring.

Step 2: Apply generous, outward pressure on the ring while holding the bead. The bead will pull out, and the ring can be slid out of the piercing (see Figure 123-1).

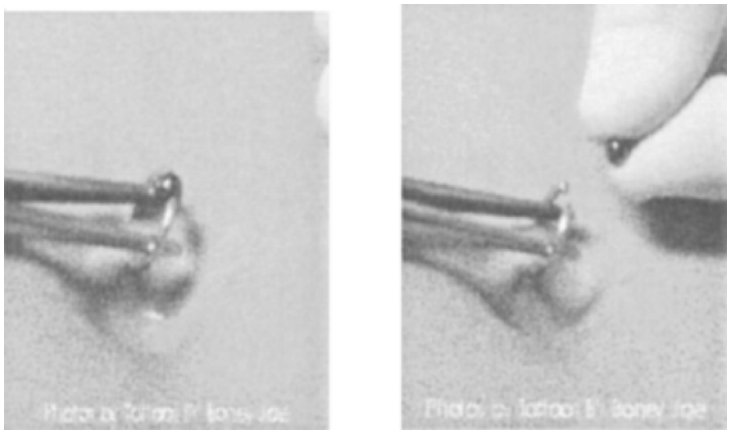

Figure 123-1.

Removal of captive bead ring.

View Image

Removing this type of ring can also be accomplished using scissors (see Figure 123-2).

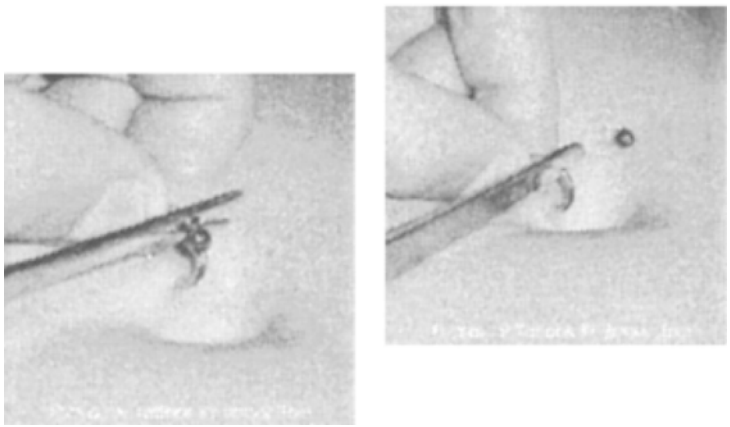

Figure 123-2.

Removal of captive bead ring us

View Image

Step 1: Lubricate the piercing with a small amount of saline and grasp the ring with scissors where the bead and the ring meet.

Step 2: Squeeze firmly to release the bead. The bead should pop out quickly, and the ring can be removed.

These tools work for smaller rings, but larger gauge jewelry may require circlip pliers or larger clamps.

Removal of the Barbells

Step 1: Lubricate the piercing with a small amount of saline and grasp each end of the barbell with a hemostat or gloved fingers.

Step 2: Unscrew in a counterclockwise motion. The bar can then be removed from the piercing once one end is removed (see Figure 123-3).

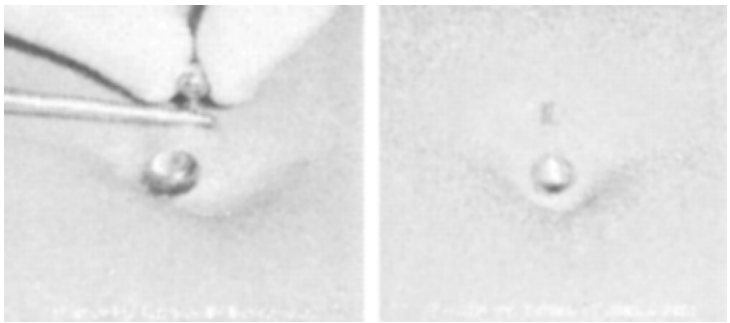

Figure 123-3.

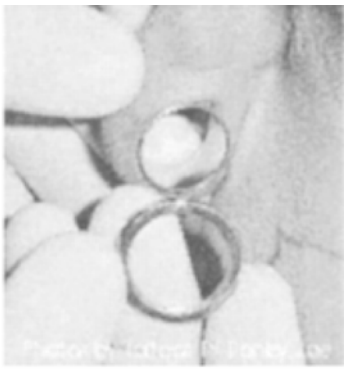
Removal of barbells.

View Image

To remove a barbell from oral piercings (see Figure 123-4), dry the area with gauze and grasp the barbell underneath the tongue. The top ball can then be unscrewed and the bar removed. Hemostats may be used to hold the barbell steady if necessary. On some jewelry, only the bottom ball will unscrew.

Figure 123-4.



Removal of barbells from oral piercing.

View Image

Removal of Plugs

There are three types of plugs that are worn almost exclusively in the earlobe where the skin has been stretched. The threaded plug is held in place by a threaded ring, usually found on the back of jewelry. The ring should be unscrewed in a counterclockwise motion, and the plug removed (see Figure 123-5).

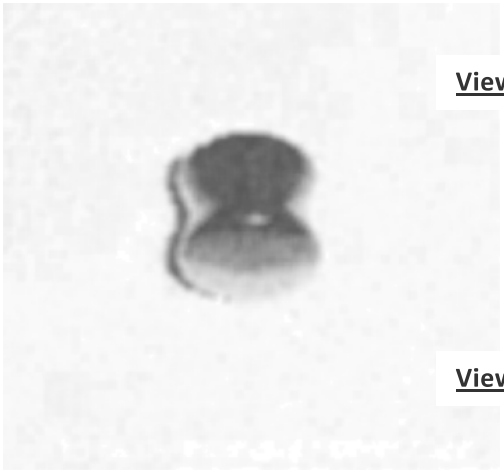


Figure 123-5.

Removal of plugs.

View Image

Flared plugs (Figure 123-6) are removed by simply pulling them out. Plugs with rubber O-rings (Figure 123-7) are removed by pulling one of the O-rings off and removing the plug.

ELECTROLYSIS

Infection Prevention Interventions

Electrolysis has the potential to spread infections. While the needle is inserted into the hair follicle and should not pierce the skin, this can occur during the procedure, contaminating the needle and introducing bacteria. This has the potential to cause skin and soft tissue infections. There have been case reports of human papilloma viruses being spread through electrolysis.[28] Additionally, electrolysis has been reported to spread *Molluscum contagiosum* virus locally in an individual.[29]

It is difficult to describe the epidemiology of disease transmission after tattooing and body piercing procedures. There have not been uniform licensure requirements for body art studios or for individuals performing the procedures, and so the reporting of infections to a public

health agency is generally limited to bloodborne diseases identified by the healthcare system. The licensure varies greatly by state. Regulations may address the age of the client, client histories, sterilization processes, single-use items, apprenticeships/training, and bloodborne pathogens training. Some states leave the regulations up to local ordinances and some have no regulations whatsoever. The enforcement of the various regulations is dependent on funding of the programs, which is also variable.[30] Many local health departments may inspect the business sites, but it is questionable whether inspectors receive adequate training about the appropriate infection prevention practices they should monitor in these nontraditional settings. Also, the frequency by which the sites are inspected is variable. Sometimes it takes an adverse event for a site to be inspected. There are many opportunities for contamination, particularly for tattooing. Many of the practices being adopted by piercing studios worldwide are based on a common sense approach, as well as guidelines offered by professional organizations such as the APP or the Piercing Association of the United Kingdom.[30]

It is much easier to identify breaks in technique that could lead to the transmission of bloodborne pathogens and other infectious diseases. The recent events of reusing single-use items in healthcare clinics are a reminder that constant education and follow-up is necessary to reinforce good practices. Modern tattoo parlors are fully aware of the bad publicity that sometimes surrounds the tattoo industry, and they are trying to build reputable businesses through the following practices:

• Sterile needles must be used for only one tattoo session, on only one client.

• The studios should use separate small containers of dye that are used on only one customer and are discarded after use.

• Needles and the tips and tubes that hold them in the machine should be sterilized in an autoclave following each use. The machine itself cannot withstand autoclaving, and so it should be placed in a plastic bag during use and disinfected between customers.

• The tattoo site should be disinfected before the procedure and dressed with an antiseptic ointment and a sterile bandage.

• The artists should wear latex or nitrile gloves to protect the clients from resident and transient flora on their hands and to protect themselves from the blood of their clients.[6] If latex is used, it is important to educate staff on petroleum-based products that react with latex, making it less effective as a barrier.

• Unsafe practices used in the past should be replaced by those identified in the Occupational Safety and Health Administration (OSHA) Bloodborne Pathogens Standard and other disease prevention guidelines.

• Education and reeducation is important to keep employees updated on current safe practices.

The licensing requirements for electrolysis vary by state. According to the American Electrology Association (AEA), there are currently 33 states with state regulation of electrology. The training requirements vary. Some states require students to do a specified number of hours training. This range of required hours is 300 to 1,100 hours. Some states will accept apprenticeships for a specified amount of time. The length of apprenticeship can be a short as 600 hours and as long as 1,600 hours. Most states require an examination. Some states pair with cosmetology licensing, and continuing education can also be a requirement for recertification. Most states also require that applicants be at least 18 years of age with a high school diploma or equivalent.[31]

The AEA has also published Infection Control Standards for the practice of electrology that explains potential risks and make recommendations regarding controls. Some of their recommendations are summarized here:

• Use appropriate hand hygiene (follow Centers for Disease Control and Prevention guidelines).

• Wear gloves during activities that might contaminate hands with blood or body fluids.

• Use single-use, sterile, disposable needles and store them in a manner that will maintain sterility.

• Properly dispose of needles to avoid sharps injuries.

• Thoroughly clean and sterilize items that are reprocessed such as forceps, phoresis rollers, and tips.

• Keep the work environment clean, well lit, and ventilated.

The infection preventionist may serve as a resource for safe practices in the community. The Health Canada guidelines are an excellent reference, detailing all the safe practices that should be part of tattoo, body piercing, and electrolysis studios.[3] The following summaries have been created from this information to provide a review of the basic infection prevention practices that should be observed in these establishments.

Worksite Design: The Shop

• Work areas should be organized to prevent cross contamination of clean, disinfected, or sterile equipment with dirty equipment.

oClean zone: procedure area, hand-washing sink, sterilized packages, disinfected and clean equipment storage

oDirty zone: contaminated equipment, utility sink, holding basins for equipment that will be disinfected/sterilized

• General requirements

oAll surfaces should be constructed of materials that are smooth, nonporous, and easily cleaned

oGood lighting and ventilation

oHot and cold running water, two sinks are highly recommended: one for hand hygiene and one for cleaning contaminated items

oCabinets or storage space (preferably enclosed) to protect supplies from dust and moisture

oPublic washroom access

• Instruments and equipment

oNeedles used for tattooing, piercing, or electrolysis must be sterile and used once per client

oReusable instruments should be smooth, noncorrosive, and constructed of materials that can be easily cleaned and sterilized (e.g., stainless steel)

oMachine controls should be foot operated

oAn ultrasonic cleaning device with a lid may be used to preclean instruments

oAn autoclave should be used for sterilization

oOffice equipment (e.g., telephones) should not be touched during a procedure. If such equipment is considered part of the procedural equipment (e.g., magnifying glass arm, treatment table), it should be covered with a disposable plastic sheath or cleaned after each client service

• Necessary supplies

oMedical-grade gloves

oSingle-use wooden tongue depressors or cotton swabs for removing creams, gels, or ointments from a bulk container into a smaller package for use on a single client

oClean linen or disposable towels for patient protection or cover for a work surface

oWrapping material and suitable containers to contain instruments for sterilization

oMetal basins or other suitable containers for dirty equipment

oChemical time/temperature and/or humidity sensitive tape, strips, or pellets for monitoring each sterilization cycle

oSpore strips or vials for testing the sterilization process weekly or monthly, as required

oLiquid hand-washing soap that is provided in nonrefillable cartridges or containers

oDetergent for cleaning

oCommercial sharps containers

oHospital-grade disinfectants

• Disinfection and sterilization practices should be in accordance with the Spaulding classification system.

• Aseptic technique, hand-washing, and barrier procedures should be in accordance with standard hospital practices.

• Skin should be inspected for signs of infection or abnormalities, then prepped with an appropriate antiseptic solution.

• Waste should be segregated and disposed of according to regulations.

• Client records should be kept for all procedures for at least the minimum time period specified by law.

• Bloodborne pathogens precautions (Standard Precautions) should be observed.

• Material Safety Data Sheets (MSDS) should be kept for all chemicals on the premises.

• All practitioners and shop employees should be trained on infection prevention and control practices to ensure a safe environment for clients and workers.

If you should need additional information on the specific infection prevention procedures for performing tattooing, body piercing, or electrolysis, details are available in the Health Canada guidelines.[3]

OCCUPATIONAL EXPOSURES

In body piercing, tattoo, and electrolysis establishments, the potential exists for occupational exposure to bloodborne pathogens. Employees should be trained to follow Standard Precautions and OSHA Bloodborne Pathogen Standards. To prevent HBV, vaccines may be offered to employees to prevent infection. A study by Hellard et al. looked at the training and knowledge among body piercing practitioners in Australia.[32] They found that there was a lack of training and knowledge regarding HCV and inconsistent cleaning and skin antisepsis protocols. These knowledge deficits have the potential to put both the practitioner and the client at risk. There should be established protocols for the procedures as well as protocols to alert practitioners on what they need to do in the event of an exposure to mitigate the risk of infection. Oberdorfer et al. reported on a trial conducted in Sydney, Australia, in 2002 in which educational intervention activities were provided to half of the tattooing/body piercing premises involved in their study.[33] No effects were found in terms of improved knowledge, but the group that received educational intervention showed a significantly greater perception of the risks of being detected and penalized for noncompliance with infection prevention guidelines.[33] This stresses the importance of standardization of certification and licensing requirements as well as site inspections.

Conclusions

Body piercing and tattooing are increasing in popularity and are considered expressions of a person's individuality. When performed by a trained professional, using established infection prevention practices, these procedures are considered relatively safe. It is important for potential clients to ask questions of the artists that will perform the procedures and to evaluate the cleanliness of the studio. There have been various reports of infectious and noninfectious complications following both procedures, but many of the risks can be minimized by the use of appropriate sterilization and disinfection practices. By providing detailed instructions on appropriate aftercare to the client, tattoo artists and body piercing professionals can further ensure a better outcome for their clients.

Future Trends

In this era of patient safety, there will be more focus on standardizing and regulating these industries and ensuring that their practitioners are well trained in infection prevention. As tracking methods for capturing adverse events related to tattoos, piercings, or electrolysis improve, the data should drive policy and regulation.

International Perspective

Although body piercing and tattooing are generally considered to be safe procedures when performed by a trained professional using good infection prevention methodology, there are concerns that these techniques may not be universally practiced in all parts of the world. Obviously, the body decoration that is being performed as ethnic identification may not be using optimal aseptic technique, but there is still a lack of training on safe practices in many countries. Even in the United States, there is no mandated

training or certification process for body piercing and tattooing artists. Much of the training is performed in existing studios, so that less-than-optimal practices may be passed on to new practitioners unintentionally. Although it is believed that each studio has the best of intentions and does not recognize that their practices may not be as safe as they could be, it is concerning that there is not a better mechanism for practice standardization throughout the world.

Access to sterilization equipment and disinfection products also varies throughout the world, and the costs associated with providing optimal care may not be appreciated by the person responsible for making a profit with the business venture. Although site infections are obvious to the client, the potential transmission of bloodborne disease would not be immediately identified, and clusters of infection may escape detection. Travelers should be warned against obtaining tattoos in countries where the knowledge of aseptic technique is not optimal. In any country, it is important for the client to evaluate the studio setup and the artist's explanation of their safe practices.

Supplemental Resources

The following resources may be accessed electronically and provide an in-depth discussion of the issues associated with body piercing and tattooing. The Association of Professional Piercers site lists their current leadership under the "Contact Us" section, and you will find that the members listed there are tremendously helpful in answering any questions you may not find on the site.

The Association of Professional Piercers. Available at: http://www.safepiercing.org.

Special thanks to Elayne Angel, Bethra Szumski, and Steve Joyner from APP for their help in learning about the art of body piercing and to Joe Clark, Master Piercer and proprietor of Tattoos by Boney Joe, Zelienople, Pennsylvania, for providing technical expertise and the photographs used in this chapter.
